Fig. 1. Mortality between birth and 21 days, by generation. Continuous line: mice at -3°C ; broken line: controls. Each point is a group mean for pairs of one generation. Vertical lines represent standard errors. The numbers of pairs are shown at the top. No control data are available for generations 3-6.

gressive increase in fecundity in the cold: in fact, the number of young born per pair did not change significantly in either temperature. The most probable sources of the improvement are (a) increased milk yield^{6,8}, (b) superior ability of the young to respond to the low temperature by increased heat production^{3,4}.

Whatever the physiological basis, the results require explanation in terms of either (1) a steady genetical change in the colony maintained at -3°C ; or (2) a cumulative maternal effect.

(1) The first hypothesis implies that the original strain was genetically heterogeneous despite its long history of sib mating (since mutation cannot account for a rapid progressive trend of the kind observed). If this were so, it would be necessary to assume that there were present genetical mechanisms which tended to maintain heterozygosity in the face of rigorous inbreeding. There are empirical grounds for rejecting this hypothesis, in the work of Deol *et al.*⁷: these authors give evidence that inbred mouse strains are genetically homogeneous, and that the formation of sub-lines is due to the occasional appearance of mutant genes which "tend to be fixed promptly in homozygous condition". The fact that the improvement continued even when the infant mortality was low is also against this hypothesis, since natural selection can occur only if the breeding of some members of each generation is diminished either by death or by reduced fertility.

There are also theoretical grounds for doubting whether heterozygosity at several loci could be maintained in an animal such as the mouse, since an excessively high loss of progeny would be required in each generation⁹.

(2) The second hypothesis implies that the change is wholly one of 'nurture'. Survival in the cold demands extensive physiological adaptation. The young not only must themselves respond to the cold environment, but also may be influenced by the adaptive adjustments made by the mother: this effect could be through the environment either in the uterus or in the nest (the nest environment includes the milk supply). The hypothesis requires that the ill-effects of rearing the females in the cold were progressively reduced through a cumulative improvement in physiological adaptation to cold. There is no

obvious argument against this, but there is little evidence to show how the change could have been brought about.

Neither hypothesis accounts for the fact that, from the seventh generation on, the infant mortality in the cold was consistently lower than in the warm. This implies that, in the long run, so far as survival during the first 3 weeks was concerned (though not in other ways), the cold environment was the superior one. Yet the infant mortality in the warm was similar to that reported by other workers; there is consequently no reason for thinking that there was anything wrong with the conditions in the warm room.

Whether the change in infant mortality was due to heredity or environment, it has implications for any experiments in which mice (and perhaps other mammals) are maintained for several generations in an environment very different from that of a control group. Just what these implications are depends on the exact nature of the change; this is being studied. The results will in any case be more fully reported and discussed later.

The work is supported by the Medical Research Council.

Presynaptic Nature of Neuromuscular Depression in the Frog

WHEN a number of successive nerve impulses arrive at a curarized neuromuscular junction, the induced end-plate potentials show a gradual decrease in size (Wedensky-inhibition, or junctional fatigue). Two different mechanisms, though not exclusive of each other, are conceivable.

(1) The amount of acetylcholine liberated at the nerve endings might be decreased, presumably in consequence of the depletion of the store of transmitter substance¹⁻⁴.

(2) The sensitivity of the end-plate to acetylcholine might be decreased as a result of the desensitizing action of the transmitter.

Recently, Thesleff⁵ reported that the latter mechanism was a main cause of the diminution of the size of the end-plate potential in the rat. In the following experiment it will be shown that, in contrast with the case in the rat, the first mechanism is the main cause of neuromuscular depression in the frog and that the latter mechanism plays only a negligible part, if any.

A recording micro-electrode was inserted at the end-plate region of a curarized sciatic-sartorius preparation of the frog. Constant quantities of acetylcholine were applied electrophoretically from a second micro-pipette containing a 1.1 M solution of the substance, which was located on one of the sensitive spots of the same end-plate. End-plate potentials were induced

Fig. 1. End-plate and acetylcholine potentials following the conditioning repetitive stimulation. In each record, the upper trace shows the membrane potential recorded from the end-plate region. In the lower trace the strength of the current through the acetylcholine pipette was monitored.

A, End-plate potential (A1) and acetylcholine potential (A2) about 0.9 sec. after repetitive stimulation.

B, End-plate potential (B1) and acetylcholine potential (B2) 11 sec. after repetitive stimulation.

Conditioning stimuli were given every 20 sec. Neuromuscular transmission was blocked by *d*-tubocurarine 3×10^{-6} . The muscle was stretched by about 20 per cent of its resting length. Resting potential was 89 mV.

Monitor calibration: '4 mV.' scale = 1.2×10^{-7} A.

by supramaximal nerve volleys. End-plate and acetylcholine potentials were recorded at various intervals after the conditioning stimuli consisting of 10 successive nerve volleys at a frequency of 50 per sec.

Fig. 1 shows that about 0.9 sec. after the conditioning stimuli the size of end-plate potential is decreased by 55 per cent compared with that of the end-plate potential which is not preceded by repetitive stimulation. The amplitude of acetylcholine poten-

tials, on the other hand, remains completely unchanged whether preceded by conditioning stimuli or not.

The amplitude of end-plate potentials and that of acetylcholine potentials at increasing intervals after conditioning stimuli are given in Fig. 2 as a percentage of amplitudes of end-plate and acetylcholine potentials which are not preceded by repetitive stimulation.

Essentially the same result was obtained from the preparation in which the activity of cholinesterase was completely inhibited by prostigmin 2×10^{-6} .

It is concluded from this experiment that the sensitivity of the end-plate to acetylcholine remains entirely unchanged even when the amplitude of the end-plate potential is markedly decreased after repetitive stimulation. This conclusion is in good agreement with the earlier suggestion^{1,2} of the presynaptic nature of neuromuscular depression, but makes a sharp contrast with the result obtained by Thesleff in the rat. The difference between Thesleff's result and ours might be due to use of a different species; or, the diminution of the response to acetylcholine after conditioning stimuli observed in the rat might have been caused by the mechanical movements, since even a very minute movement suffices to abolish completely the response to acetylcholine.

We wish to thank Prof. H. Kumagai and Prof. S. Ebashi for their encouragement and advice.

Actions of the Decarboxylase Inhibitor, α -Methyl-3,4-dihydroxyphenylalanine, in the Dog

Alpha-methyl-3,4-dihydroxy-DL-phenylalanine was shown by Sourkes¹ to be a potent inhibitor of the decarboxylation of 3,4-dihydroxyphenylalanine *in vitro*. This action was confirmed by animal studies in which the pharmacological actions of 3,4-dihydroxyphenylalanine and 5-hydroxytryptophan were decreased by administration of this compound^{2,3}. Further evidence of the activity of α -methyl-3,4-dihydroxy-DL-phenylalanine *in vivo* was obtained by Smith⁴, who reported that levels of serotonin in the brains of mice were decreased after parenteral administration of this compound. More recently, Oates *et al.*⁵, in this Laboratory, observed a decrease in the formation of serotonin, tryptamine and tyramine from the precursor amino-acids when 1.0-6.0 gm./day of α -methyl-3,4-dihydroxy-DL-phenylalanine were administered to hypertensive patients. Associated with this decrease in amine production was the development of transient sedation and a lowering of the blood pressure.

In the present investigation, intravenous administration of α -methyl-3,4-dihydroxy-DL-phenylalanine was found to decrease the blood pressure and to produce sedation of the unanesthetized dog, thus making it possible to study these actions of the inhibitor by pharmacological and biochemical techniques not

Fig. 1. Femoral arterial pressure of an unanesthetized dog before (above) and 4 hr. after intravenous administration of 100 mgm./kgm. of α -methyl-3,4-dihydroxy-DL-phenylalanine. The scale to the left of the upper tracing is in mm. mercury. The heavy vertical lines signify 10-sec. intervals.

applicable in man. Blood pressure was recorded from the femoral artery in five unanesthetized, semi-trained, mongrel dogs by direct puncture or by cannulation of the artery under local anesthesia. The pressures were measured electronically by means of a Statham transducer and Grass polygraph. In each animal, intravenous administration of 100–200 mgm./kgm. of α -methyl-3,4-dihydroxy-DL-phenylalanine produced reductions in arterial pressure ranging from 30/10 to 60/30 mm. mercury (Fig. 1). The hypotension did not begin until 2–3 hr. after drug administration and the maximum effect was usually not observed for 4–6 hr. The blood pressure returned to normal values within 24 hr., and in three of the animals repeated administrations of α -methyl-3,4-dihydroxy-DL-phenylalanine on 2–7 subsequent days produced equivalent hypotensive effects. At the time the blood pressure was reduced, there was no consistent change in heart-rate, no alteration in the response to tilting the animal through 90°, and no relaxation of the nictitating membrane. In most experiments, the animals appeared to be quietened by the inhibitor, but they were easily startled by noise. Injections of saline in the same animals had no effect on blood pressure recorded under identical conditions.

Heart contractile force was measured by a Walton strain gauge arch in seven vagotomized, anesthetized, open-chest dogs as previously described⁶. The pronounced and prolonged increments in heart contractile force produced by 10–20 mgm./kgm. of L-3,4-dihydroxy-DL-phenylalanine or DL-metatyrosine, injected intravenously, were found to be completely inhibited by intravenous administration of 100–200 mgm./kgm. of α -methyl-3,4-dihydroxy-DL-phenylalanine. This total inhibition remained for 30 min. after drug administration and then gradually decreased so that the responses of 3,4-dihydroxy-DL-phenylalanine and metatyrosine were essentially back to control-levels in 4–6 hr. In these and similar experiments, the cardiovascular effects of 1-norepinephrine, dopamine

and tyramine were not significantly altered. The increments in heart-rate and contractile force produced by stimulation of the presynaptic fibres to the stellate ganglion were also not blocked by administration of α -methyl-3,4-dihydroxy-DL-phenylalanine, indicating that the function of the sympathetic ganglion and nerves was intact.

In order to correlate the pharmacological actions of the inhibitor with biochemical changes, preliminary determinations of decarboxylase inhibition and serotonin-levels in the brain (caudate nucleus) and norepinephrine in the heart (atria) were obtained in thirteen additional dogs. Eight dogs were killed by bleeding under barbiturate anesthesia at 3, 5, and 24 hr. after intravenous administration of α -methyl-3,4-dihydroxy-DL-phenylalanine as shown in Table 1. Five dogs were killed in a similar manner to serve as controls. Serotonin-levels and decarboxylase inhibition were determined by previously described techniques⁷. Trichloroacetic acid extracts of tissues were purified by absorption on alumina and the eluates were assayed fluorimetrically for norepinephrine by a modification of the trihydroxyindole method⁸. The high fluorescence of α -methyl-3,4-dihydroxy-DL-phenylalanine or of its metabolites remaining in the tissues prevented determination of norepinephrine levels in the 3- and 5-hr. samples. Accordingly, two additional experiments were carried out with a related decarboxylase inhibitor, α -methyl-3-hydroxy-DL-phenylalanine (α -methyl metatyrosine), which does not interfere with norepinephrine determinations.

Table 1. EFFECTS OF DECARBOXYLASE INHIBITORS ON LEVELS OF SEROTONIN IN THE BRAIN AND NOREPINEPHRINE IN THE HEART

No. of dogs	Inhibitor	Dose (mgm./kgm.)	Time (hr.)†	Serotonin (caudate nuclei) (μ gm./gm.)	Norepinephrine (atria) (μ gm./gm.)
5	Control	—	—	1.03	2.41
2	α -methyl dopa*	200	3	0.43	—
2	α -methyl dopa	200	5	0.78	—
2	α -methyl dopa	200	24	1.13	1.88
1	α -methyl dopa	500	24	1.00	1.77
1	α -M.M.T.†	200	5	0.41	1.74
1	α -M.M.T.	400	5	0.50	1.53

* α -methyl-3,4-dihydroxy-DL-phenylalanine.

† α -methyl-3-hydroxy-DL-phenylalanine.

‡ Time in hours after administration of inhibitors.

The results of the serotonin and norepinephrine determinations are shown in Table 1. As may be noted, there was a decrease in the serotonin-levels in the brain to values 60 per cent lower than those of the control animals in 3 hr., but in the 5-hr. specimens the serotonin-levels had returned to 80 per cent of control values. These changes in serotonin content appeared to be related to decarboxylase inhibition for in 3 hr. there was 40 per cent inhibition, but there was no inhibition demonstrable in the 5-hr. specimens. These *in vitro* determinations of decarboxylase inhibition, therefore, correlated well with the inhibition of the cardiac actions of 3,4-dihydroxy-DL-phenylalanine and metatyrosine *in vivo*. Norepinephrine-levels were decreased slightly 5 hr. after α -methyl-3-hydroxy-DL-phenylalanine and 24 hr. after α -methyl-3,4-dihydroxy-DL-phenylalanine. Serotonin-levels and decarboxylase inhibition were approximately the same in the specimens obtained 5 hr. after administration of α -methyl-3-hydroxy-DL-phenylalanine as in the specimens obtained 3 hr. after α -methyl-3,4-dihydroxy-DL-phenylalanine.

The results of this work indicate that the pharmacological effects of α -methyl-3,4-dihydroxy-DL-

phenylalanine in the dog do not appear to be related to decreased function of the peripheral sympathetic nerves or to an adrenergic blocking action. The preliminary biochemical work demonstrates that α -methyl-3,4-dihydroxy-DL-phenylalanine is a potent decarboxylase inhibitor and decreases serotonin-levels in the dog. These changes, however, did not appear to be temporally related to the pharmacological effects in the unanesthetized dog. The decrements in norepinephrine-levels in the heart were not pronounced and were probably of little pharmacological significance since the response of the heart to stimulation of cardiac sympathetic nerves was unaltered. Additional work is being carried out to determine whether the pharmacological actions of α -methyl-3,4-dihydroxy-DL-phenylalanine and similar compounds are related to decarboxylase inhibition.

We wish to thank Merck, Sharp and Dohme for the supplies of α -methyl-3,4-dihydroxy-DL-phenylalanine and α -methyl-3-hydroxy-DL-phenylalanine.

HÆMATOLOGY

Glucose-6-phosphate Dehydrogenase Deficiency, Haptoglobin Groups, Blood Groups and Sick Cell Trait in the Bantus of West Belgian Congo

SINCE the demonstration that red blood cells of almost 10 per cent of American Negroes are deficient in glucose-6-phosphate dehydrogenase^{1,2}, one can suppose that the same defect exists in West Africa. The semi-quantitative test described by Motulsky³ is particularly suitable for a rapid and efficient screening of the male subjects in a given population.

We made such a survey among the adult male Bantus of Leopoldville, capital of the Belgian Congo. More than 75 per cent of the inhabitants of this town originated from the west parts of the country. Among 522 adult males, we found 112 deficient subjects (21.5 per cent). This percentage is one of the highest hitherto discovered in adult males (Table 1). We have found by our own experience that, among deficient males, the glutathione stability test according to Beutler⁴ gives the same results as the screening test proposed by Motulsky.

Table 1. RACIAL INCIDENCE OF GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY IN MALE SUBJECTS

Origin	Deficient percentage	Screening method
Sardinians (ref. 5)	8	Glutathione stability test
American Negroes (ref. 1)	8.8	Glutathione stability test
Iranians (ref. 6)	9.8	Glutathione stability test
Non-Ashkenazic Jewish (ref. 7)	11.2	Glutathione stability test
Nigerians (ref. 8) (two tribes)	6.14-16.9	According to Motulsky
Congolese Bantus	21.5	According to Motulsky

To obtain a more complete view of the genetic pattern of these Bantus, we performed a survey, determining in each of a group of 150 adult male subjects the following genetically inherited characteristics of the blood: A, B, O and D blood groups, sickle cell trait (paper and starch-gel electrophoresis at pH 8.6 coupled with falciformation test), haptoglobin groups (according to Laurell⁵ on starch-gel electrophoresis) and glucose-6-phosphate dehydrogenase activity in erythrocytes (according to Motulsky).

Table 2

Origin	Phenotype percentage				Origin	Phenotype percentage		
	A	B	AB	O		D	d	D ^a
Congolese male Bantus	26.2	21.2	5.8	46.8	Idem	94	3.3	2.6
Belgians (Hubinont, ref. 10)	43.3	7.9	3.4	45.4	Belgians (Mourau, ref. 11)	82.4	17.6	

As already known, the phenotypes B and D are more frequent among Bantus than among Caucasians (Table 2). Nevertheless, the genes of A, B, O, and rhesus blood groups are not closely linked with the genes responsible for the glucose-6-phosphate dehydrogenase deficiency, as indicated by a χ^2 test.

Phenotype number	AB	A	B	O
Non-deficient	7	30	28	58
Deficient	2	11	5	15

$$\chi^2 = 1.5, P \text{ between } 0.7 \text{ and } 0.5.$$

The Congolese Bantus have one of the highest sickle cell trait incidence in the world. Figures of 25-30 per cent in the west and central parts of Belgian Congo are quoted by Vandepitte¹². In our group of 151 male adult Bantus, we found 33 subjects with the genotype AS (21.8 per cent). Although almost equal in incidence, the enzyme deficiency and sickle cell trait do not appear to be linked.

Tested number	AS	AA
Non-deficient	25	93
Deficient	8	25

$$\chi^2 = 0.376, P \text{ between } 0.7 \text{ and } 0.5.$$

We did not find any person belonging to the haptoglobin genotype 0-0, as described by Allison¹³. It appears from the literature that the percentage of haptoglobin groups varies according to different races. Congolese Bantus present the highest percentage for haptoglobin group 1-1 and the lowest for haptoglobin 2-2 hitherto described (Table 3). There is no apparent linkage between the genes of glucose-6-phosphate dehydrogenase deficiency and those of haptoglobin groups.

Phenotype number	1-1	1-2	2-2
Non-deficient	62	42	5
Deficient	20	11	0

$$\chi^2 = 1.72, P \text{ between } 0.3 \text{ and } 0.5.$$

Table 3. RACIAL INCIDENCE OF HAPTOGLOBIN GROUPS

Origin	Phenotype percentage			Gene percentage	
	1-1	1-2	2-2	1	2
Indians (ref. 14)	1.8	14.6	81.7	0.09	0.91
Bushmen (ref. 15)	10.8	36	53	0.29	0.71
Swedish (ref. 16)	15	47	38	0.38	0.61
Ivory Coast (ref. 17)	49	42	9	0.70	0.30
Congolese Bantus	59	37.5	3.5	0.77	0.22

Summarizing, we can assert that Congolese Bantus are characterized by a high incidence of S haemoglobin, glucose-6-phosphate dehydrogenase deficiency, haptoglobin 1, B and D blood group genes. These facts support the hypothesis of poor admixture of foreign blood in this population.

This particular genetic pattern induces some pathological consequences and raises a few questions.

(1) In the Bantu, the incidence of haemolytic disease of the newborn by anti-D iso-antibodies is quite uncommon.

(2) Clinicians must bear in mind the possibility of haemolytic crisis in patients lacking glucose-6-phosphate dehydrogenase, induced by drugs like 8-aminoquinolines, naphthol derivatives, sulphones and nitrofurazone. This last-named drug is certainly dangerous as demonstrated by one of us in a Bantu patient¹⁸. As the enzyme activity in erythrocytes of deficient Bantus is 1/5-1/8 of a normal control (Sonnet, J., and Haumont, A., unpublished work), it is likely that deficient Bantus are not so sensitive as Caucasian males, whose enzyme deficiency is almost complete.

(3) The parallelism between the high incidence of sickle cell trait and enzymatic deficiency in the Bantus, as compared with American Negroes, suggests that, in a tropical environment, an identical underlying cause could exert a positive selection on both kind of carriers. As suggested by Motulsky, the mechanism of this advantage could be a protection against *Plasmodium falciparum* infection.

Hæmagglutination of Cells treated with Antibiotics

PREVIOUSLY, we directed attention to the occurrence in certain sera of an antibody-like factor capable of causing hæmagglutination of group O, Rh-negative red cells modified by exposure to penicillin^{1,2}. The reaction appears to be specific and is inhibited by preliminary mixing of the sera with penicillin.

We have extended this work to try to determine the presence of hæmagglutinating factors for erythrocytes modified by other antibiotics. Negative results were obtained with streptomycin, dihydrostreptomycin and tetracycline. However, from a series of 1,700 routine hospital blood bank sera tested, six were found capable of agglutinating chloramphenicol-modified cells. Titres ranged from 1/2 to 1/128, when the sera were diluted in 0.85 per cent saline and incubated at 37.0° C. for 1½ hr. followed by spinning at 1,000 rev./min. for 1 min. before reading.

Sensitized cells were prepared by adding 250 mgm. of chloramphenicol to 4.0 ml. of fresh blood in 4.0 ml. of Alsevers solution. Incubation at 37.0° C. for 1 hr. was followed by storage at 4.0° C. overnight. For use, 2.0 ml. of suspension were washed four times in 20.0 ml. of saline and resuspended to make an approximate 10 per cent suspension. Red cells exposed to a mixture of penicillin and chloramphenicol were agglutinated in the presence of each homologous positive serum.

The hæmagglutinin against chloramphenicol-modified cells appears to be similar to that against penicillin-modified cells. Both are stable on heating, and the reaction is inhibited in the presence of the appropriate antibiotic. In each instance dilution in 30 per cent bovine albumin solution leads to an approximate four-fold reduction in titre. None of the sera against chloramphenicol-modified cells gave a positive antiglobulin test. Solutions of urea (20 per cent), sodium salicylate (5.0 per cent), and glycerol in saline (20 per cent) inhibited both reactions, suggesting that the nature of the physical associative interaction between the molecules may be one of hydrogen bonding.

We considered previously the possibility of an immune origin for the penicillin-modified cell hæmagglutinin, penicillin acting as a hapten in conjunction with some tissue protein¹. Of 30 such sera 28 were derived from patients with a history of previous penicillin therapy. However, of the six sera agglutinating chloramphenicol-modified cells, five were obtained from patients with no previous history of chloramphenicol treatment. The highest titre serum (1/128) came from a patient aged six years who had apparently never received any antibiotic therapy. It may be that there has been previous antigenic stimulation by some substance or compound with a common determinant group to chloramphenicol or, alternatively, the reaction might be due to the presence of some naturally occurring factor in certain sera. If so, the specificity of the reaction seems remarkable. One serum will not agglutinate erythrocytes modified by the heterologous antibiotic, nor will penicillin inhibit the agglutination of chloramphenicol-treated cells with the homologous serum and vice versa. If not of immune origin, the apparent narrow specificity of the reaction requires further elucidation.

By starch-gel electrophoresis we have demonstrated hæmagglutinating activity in the pre-albumin moiety of positive sera against penicillin-modified cells. In

only one of 24 sera have we found activity in the γ -globulin fraction, and this serum gave a positive antiglobulin test in addition to having the characteristic agglutinating fraction in the pre-albumin zone. The suggestion is made that some antibiotics may function as haptens and produce true immune haemagglutinin of γ -globulin type, but that certain sera may contain an additional fraction in the pre-albumin moiety which may or may not be of immune origin. The nature and further characteristics of this factor are under investigation.

Separation of Human Serum Albumins

THE presence of several protein components in human serum albumin was recently demonstrated¹⁻³ by two-dimensional zone electrophoresis (filter paper followed by starch gel)⁴. Their identity with albumin was determined by two-dimensional zone electrophoresis³. The proteins are not related to those described by Knedel⁴ or by Gitlin *et al.*⁵. During our work on normal human sera, several new proteins were observed which had the same mobility as albumin by filter paper electrophoresis (at pH 8.6), but which when subjected to electrophoresis in starch gel in a discontinuous system of buffers⁷ migrated more slowly than albumin. These proteins can be divided into two main groups: the members of the first group are immunologically related to albumin and one of them is present in sera in about 50 per cent of all normal adults and children. These proteins will be referred to as 'albumin-like proteins'.

A second group of proteins was also found which possessed a mobility on filter paper similar to, but not identical with, that of albumin. They migrate at the same rate as the 'slow' portion of the albumin and in

starch gel can be separated from albumin only in a discontinuous system of buffers. These proteins are not immunologically related to albumin and will be referred to as 'quasi-albumins'. Their presence in sera was found in 61 of the 64 individuals screened.

Proteins of either or both these groups may be present or absent in a serum for a given individual. Fig. 1, *a*, *b*, *c*, shows diagrammatically the three possible combinations of the occurrence of these proteins. A detailed description of the distribution and some of the properties of the proteins will be given elsewhere.

PATHOLOGY

Spontaneous Cytomegalic Inclusion Body Disease Involving Lacrimal Glands of Caesarian-derived (so-called) Pathogen-free Rats

HISTOLOGICAL study of lacrimal glands in laboratory rodents revealed cytological changes, for example, nuclear polymorphism and inclusions characteristic of cytomegalic inclusion body disease in rats of the Sprague-Dawley strain; no other organs were involved. Lesions occurred in both intra- and ex-orbital glands of males only at an age of six months or older and with an incidence of 100 per cent. Similar observations have recently been published for eight rat colonies of different geographical locations¹. The disease is apparently widespread among laboratory rats. Guinea pigs, a variety of mouse strains, both golden and Chinese hamsters, Wistar and Fisher rats, either commercially obtained or bred and raised in the Roscoe B. Jackson Laboratory, were free of the disease.

Our Sprague-Dawley colony was derived from stock animals purchased several years ago from a local breeding farm. For a number of years now, this breeder has since specialized in the production of Caesarian-derived pathogen-free animals. Routinely Caesarian-derived Sprague-Dawley pups are foster-suckled on germ-free Lo-bund strain mothers (alpha-colony) and on attaining breeder size

Fig. 1. Diagrams (traced from photographs) of two-dimensional zone electrophoretic patterns of human sera showing the separation of albumins (only albumin(s) and α -1-globulin regions shown). *a*, position of the 'albumin-like' protein; *b*, positions of 'quasi-albumins'; *c*, pattern of an individual with both groups of proteins

transferred to pathogen-free surroundings. Caesarian sections are performed in sterile plastic isolaters ('Trexler' type) and pathogen-free conditions for Caesarian-derived Sprague-Dawley breeders maintained by an elaborate barrier system (sterilizer and lock system). Eight generations of pathogen-free Caesarian-derived Sprague-Dawley rats have so far been obtained, interrupted only by introduction of new germ-free Lobund rats.

Pathogenic bacteria and parasites have never been demonstrated from any of the Caesarian-derived Sprague-Dawley rats. Lacrimal glands, however, from both males and females (100 per cent) disclosed cytomegalic inclusion body disease at about six months or older. Transmission experiments were conducted with cell-free filtrates prepared by grinding glands with pestle and mortar, 'Carborundum' and tissue culture fluid (dilution 1:10) fortified with aqueous penicillin-streptomycin, centrifuged at 3,000 r.p.m. for 30 min. and filtered through bacteria-tight EK-Seitz filter pads. Sprague-Dawley new-borns were inoculated intraperitoneally, 0.1 ml., and intracerebrally, 0.03 ml. Death of 20 per cent occurred within one month from systemic cytomegalic inclusion body disease. Surviving animals, both males and females, killed at intervals of 55, 63 and 71 days, showed extensive lacrimal gland involvement only. Similarly inoculated new-born mice remained healthy and no microscopic lesions were detected.

The problem of viruses in both pathogen- and germ-free animals should be investigated systematically and adequate tests devised for virus detection. Although it is possible to raise animals in the absence of bacteria, protozoa and helminths, elimination of all viruses may be more difficult. It seems significant that at the Lobund Institute filtrable agents had been isolated from caeca of rats that were raised germ-free for several generations². Tentative identification of these agents classified them serologically in the group of ECHO viruses. Also, at the National Institutes of Health, from the salivary glands of germ-free rats an agent was isolated that could be propagated on rabbit kidney cells³.

From evidence cited it would seem that the pathogen- and germ-free state does not necessarily apply to viruses. As shown here, so-called pathogen-free animals may in fact contain infective viruses. Although viruses may be occult both clinically and microscopically, viral antibodies may or may not be detectable in infected host's serum. The presence or absence of humoral antibodies to cytomegalic inclusion body disease virus in so-called pathogen-free Sprague-Dawley rats is under investigation; also, attempts are being made to find out the virus state prevailing in this disease as compared with latent murine lymphocytic choriomeningitis and swine influenza in which neither virus nor viral antibodies are detectable by direct means. Transmission of the virus in pathogen-free rats has to be studied from an epidemiological viewpoint; it may enter postnatally (for example, viruria, ocular discharge) or prenatally by way of placental transfer (following viraemia, for example, herpes). In pathogen-free rats virus multiplication does indeed occur in lacrimal glands of females, but the presence of virus in conventional females appears to be masked. Morphological studies with the light- and electron-microscope will be presented in a separate description of the fine structure, as well as pathogenesis of inclusions.

This investigation was performed in part during tenure of appointments at the Children's Cancer

Research Foundation and the Departments of Pathology, The Children's Medical Center and Harvard Medical School, Boston, Massachusetts.

Schistosomiasis and Urinary β -Glucuronidase Activity

Boyland, Wallace and Williams¹ have shown that the activity of urinary β -glucuronidase is increased in patients suffering from bladder cancer and suggested that 'spontaneous' urinary bladder cancer could be caused by unmasking carcinogens which were inactive as β -glucuronides, but active when liberated by β -glucuronidase in the urine.

Bladder cancer is not uncommon in East Africa. The Cancer Registry of the Kampala Cancer Research Committee has noted 68 cases out of a total of 1,800 cancer cases over the past 4 years.

The role of schistosomiasis in the aetiology of bladder cancer is controversial², and as part of a programme of investigations into the background of cancer in East Africa, the effects of schistosomiasis on urinary β -glucuronidase activity are being studied. 24-hr. samples of urine are collected and the β -glucuronidase activity is estimated by a slight modification of the method of Boyland, Gasson and Williams³.

Preliminary results on a limited number of male East African natives showed that the normal range of activity was fairly narrow and was lower than that quoted by Lewis and Plaice⁴ for Europeans on a units per ml. basis, but slightly higher when expressed as activity per 24 hr.

The urine of patients suffering from intestinal schistosomiasis (*Schistosoma mansoni*) showed an increase in activity above the normal range and those with urinary schistosomiasis (*S. haematobium*) showed a well-marked increase.

Table 1. URINARY β -GLUCURONIDASE ACTIVITY

Group	N	Units/ ml.	S.D.	Units/ 24 hr.	S.D.
African normals	18	0.95	0.29	1,475	120
<i>S. mansoni</i>	8	1.59	0.91	1,970	573
<i>S. haematobium</i>	7	3.08	2.18	4,560	1,710
European normals ⁴	32	1.05	0.55	1,405	893

After treatment with 'Nilodin' (lucanthone hydrochloride, Burroughs Wellcome) or sodium antimonite tartrate, the activity of the enzyme dropped rapidly and, in cases where the series were long enough, reached the normal range, and in one case was still normal after 58 days. This drop was well marked in the *S. haematobium* series, but longer series are required for *S. mansoni*. Details of the longest series are given in Table 2.

Since urinary schistosomiasis is accompanied by haematuria, two cases of sterile haematuria unassociated with schistosomiasis were studied. Both gave results which were within the normal range. Exten-

Induction of Tumours by Polyoma in Adult Hamsters

THE relative non-susceptibility of adult versus new-born or very young animals to tumour induction by certain viruses has been interpreted as the expression of either of two possibilities: (1) presence in the young animal of cells intrinsically more susceptible to the virus infection and to the proliferative response; (2) lack in the young animal of an adequate immunological response.

In the case of tumour induction by polyoma, much emphasis has been placed on the fact that it is the undifferentiated mesenchymal cells in the new-born hamster which are susceptible to the proliferative response¹. Thus the proliferative response to infection and the appearance of the tumour would depend on the availability of such cells. Results presented here show that the tumour can be induced by polyoma in adult hamsters, and special attention has been paid to the influence of the immunological process on the outcome of polyoma infection in terms of tumour production. Twenty male Lakeview hamsters 6 weeks old were divided into two groups: 10 animals were inoculated subcutaneously and 10 intra-peritoneally with a single dose of 0.2 mm. of a tissue culture preparation of polyoma virus (M-11-9A). Of the group inoculated intra-peritoneally, 5 died between the 8th and 15th week after inoculation; only one could be autopsied, and the cause of death was found

to be a massive intraperitoneal haemorrhage, originating in a broken haemorrhagic cyst in the liver; a similar picture was found in another animal dying 24 weeks after inoculation. In this same group, one animal, 13 months after receiving the inoculum, developed a subcutaneous nodule in the left flank which rapidly enlarged, reaching a diameter of $5 \times 3.5 \times 5$ cm. In no other areas were proliferation or necrotizing lesions observed. In the group inoculated subcutaneously, 3 animals were lost; 4 developed subcutaneous tumours 24, 35, 36, and 44 weeks after the inoculation, respectively. The tumours were very similar to those observed after inoculation in new-born hamsters, being characterized by large, haemorrhagic necrosis with very pronounced vascular formations in the viable part. The remaining 4 animals in the two groups were killed 14 months after inoculation and failed to show proliferative lesions.

In summary, 7 out of 11 hamsters which were inoculated at 6 weeks of age and in which necropsy could be done showed tumours of the liver or of the subcutaneous tissue 3-14 months after inoculation. No other tumours were found in any other organ, suggesting that the tumour had developed at the site of inoculation. The tumours were in all respects identical to those observed in new-born animals, and, in the case of the subcutaneous lesions, grew very rapidly. Haemagglutinin-inhibiting antibodies were found in all 7 of the animals tested, 3 with tumours and 4 without tumours at 11 and 14 months after the virus inoculation. Thus the only difference between new-born and adults after an equal amount of virus inoculation appears to be that in adults the latent period preceding the appearance of the tumour is greatly prolonged and that the tumour appears only at the site of inoculation. Cells capable of proliferative and neoplastic response to polyoma must, then, be present and available to the virus in the adult animal as well—probably throughout its life—although it cannot be excluded that the number and the areas of these cells may be decreased in the adult animal. It would seem that the difference between the new-born and adult animals can be better explained on the basis of immunological activity. Several observations point in this direction: high titres of polyoma haemagglutination-inhibiting antibodies are reached in the adult hamsters by the 4th-5th day, while in the new-born similar titres are found only at the 6th-7th day (Defendi, V., unpublished work); inoculation of adult lymphoid tissue in the new-born

before the virus is given increases the latency period before tumour appearance and decreases the actual number of tumours per animal²; when the lymphoid tissue inoculated originated from animals with antibodies to polyoma, the actual incidence of tumours decreases by 60 per cent, with tumours present only at the site of inoculation (Defendi, V., unpublished work). Briefly, when inoculated with adult lymphoid tissue, the new-born hamster responds to the polyoma in much the same way as the adult. One attractive hypothesis that could be formulated is that in the adult animal the considerable replication of the virus found in the new-born³ does not occur, or that the virus is rapidly neutralized, decreasing the probability of tumour initiation in organs remote from the site of inoculation. It should also be kept in mind that the virus concentration at equal inocula is much lower in the large adult animal than in the new-born.

In relation to the problem of new-born versus adult susceptibility to polyoma, it has been found in another animal (mouse) that adult salivary gland *in vitro* is just as susceptible to tumour induction by polyoma as is the foetal gland, and that X-ray treatment makes the adult mouse susceptible to the oncogenic action of polyoma⁴.

HISTOLOGY

Mineralization of Rat Enamel

THE initial stages of the mineralization of tooth enamel have been studied using electron microscopical techniques applied to ultra-thin sections of developing molars and incisors of 1-10-day-old white rats (*Rattus norvegicus*). The specimens were fixed in either Palade's¹ or Dalton's² fixative, embedded in 'Araldite' and cut without demineralization using a diamond knife.

Tooth enamel is a highly mineralized tissue consisting of tightly packed orientated apatite crystals in intimate association with an organic substance 75 per cent of which contains citric acid, peptides and a glycoprotein, the remainder being a protein of the keratin type. There is considerably more mineral than organic matter, the mineral contributing approximately 96 per cent by weight, organic material approximately 1.5 per cent and the rest water.

It is generally accepted that the keratinous organic matrix of the enamel is fibrous and that its formation precedes the mineralization process. The exact role of the ameloblast cell in enamel formation is a matter still under consideration. I believe³ that fibrillogenesis occurs extra-cellularly, the fibres forming from a granular precursor substance which is elaborated and secreted by the ameloblasts, the

Fig. 1. Diagram of amelogenesis

granules being discharged from the formative end of the cell into the extra-cellular environment. This concept is illustrated diagrammatically in Fig. 1. The newly secreted organic material in the extra-cellular region between the cells appears first to consist of granules with an electron density equal to that of the intra-cellular 'Palade' granules. Some granules then become arranged in poorly defined columns giving rise to what appear to be orientated fibres. An abrupt change to very electron dense fibres marks the next stage in enamel formation (Fig. 2). In an earlier publication⁴ I designated the region undergoing this change as the 'formative front' of the enamel matrix. This 'front' is marked by a striking contrast between the granules (diam. 50-70 Å.) which have a low electron scattering capacity and fibres (50-100 Å. $\times$ 0.1 μ -1.0 μ) (Fig. 2) which have a much greater electron-scattering property. The fibres, which have a periodicity of 50-70 Å., become arranged in parallel rows, the strands of which appear to be cross-linked in places by electron-dense granules; this results in an appearance rather like the rungs of a ladder. In the depths of the enamel where mineralization is more advanced, both granules and fibres are replaced by 'tape-like' crystals which give a diffraction pattern characteristic of apatite. The transition from fibres to 'tape-like' crystals, which might be expected to be a gradual process, is difficult to detect with certainty in 'bright-field' electron micrographs.

Diffraction patterns characteristic of apatite were obtained from selected areas of the formative front of the enamel matrix and from various places in the deeper layers of the newly formed enamel up to 30 μ from the formative zone (positions A and B, Fig. 1). A progressive change from extremely small crystallites of approximately 100 $\times$ 500 Å., to larger crystallites of approximately 500 $\times$ 1000 Å., was calculated from the angular breadth of the diffracted beam from the 002 and 300 crystal planes. The smallest crystallites are situated in the electron dense region of the formative front of the enamel matrix (Fig. 2) whereas the larger crystallites are situated away from the

formative zone in the deeper layers of the enamel matrix.

Crystallite size calculated from the orientated electron diffraction patterns is greater than the observed size of the electron-dense particles (50–70 Å.) associated with the electron-dense fibres (Fig. 2). Calculation of crystallite size from the breadth of diffraction lines is most accurate when applied to diffraction patterns from cubic crystals where the crystallite size falls within the range 100–1000 Å.⁵ Cubic and non-cubic crystals below this size-range may therefore give diffraction patterns having poor intensity, and a diffuseness which contributes to large errors in calculations of crystallite size.

By interposing a small aperture below the object plane in such a way as to permit the passage of only part of the diffracted electron beam, it is possible to produce a 'dark-field' diffraction image which shows the position and size of those crystallites suitably orientated in respect to the electron beam. Such an image appears as a bright point on a dark background. Measurements of the crystallites visible in dark-field micrographs of the formative front reveal a size-range of 50–100 Å. in the zone nearest to the forming front. Moreover, the bright regions in dark-field correspond in position to the electron-dense regions in bright-field electron micrographs.

From the evidence provided by the diffraction patterns, and both dark-field and bright-field electron micrographs, it is concluded that the abrupt change to a high electron density of the fibres at the formative front is due to the multiple deposition of very small apatite crystallites which form centres from which

Fig. 2. 'Mineralizing front', the junction between extra-cellular granules and electron-dense fibres, region A in Fig. 1

Fig. 3. Tape-like crystals of enamel in a more advanced stage of mineralization, region B in Fig. 1

further crystal growth takes place. This growth leads to the formation of the 'tape-like' crystals which can be obtained from the deeper layers of the enamel (Fig. 3). As a result of these observations I would now prefer to call this region of changing electron density the 'mineralizing front' rather than the formative front of the enamel matrix.

It has been suggested by Frank and Sognnaes⁶ that in enamel mineralization, crystal nucleation and growth are by epitaxy with the organic matrix. This may well be true since in dark-field electron micrographs small crystals can be detected spaced by regular intervals. These intervals may presumably represent the position of some structure which is not opaque to electrons and which could therefore represent the position of the organic material. Epitaxy could also explain the particularly high degree of orientation of the apatite crystals in different regions of tooth enamel. Crystallization by epitaxy commencing from multiple centres could also influence the mode of crystal growth and perhaps regulate size and packing of the crystals.

RADIOBIOLOGY

Radioactivity in Wool

WITH the development of highly sensitive γ -ray detectors, it has become possible to carry out non-destructive measurements of the low levels of γ -ray activity emitted by various biological materials. Since γ -ray measurements may be made rapidly without any special preparation or modification of the material measured, the application of this technique to agricultural research problems has much to recommend it. The advantages of the non-destructive γ -ray measurement technique appear to justify exploratory research to determine if such measurements may be used to estimate other factors to which they may be related¹.

In the course of such a line of exploratory research γ -ray measurements were made on raw and scoured wool. A recently developed low-level γ -ray detector employing plastic scintillators was used in this work². Simultaneous two-channel operation was used in making γ -ray radioactivity measurements. The upper channel was set to measure γ -radioactivity of from approximately 1.2 to 2.5 MeV. energy. The lower channel measurements represented γ -radioactivity of from approximately 0.6 to 1.0 MeV. energy plus a substantial spill-over of counts from the upper channel energy band. When a standard consisting of 1.00 lb. of potassium chloride mixed with 13.00 lb. of granulated sugar was counted using these channel settings, the net counting-rate for the potassium-40 γ -radioactivity in the lower channel was approximately 80 per cent of the net counting-rate observed in the upper channel. Since the resolution of our system is not adequate to identify unknown γ -ray emitters, no corrections for spill-over have been applied in Table 1.

Table 1. γ -RAY RADIOACTIVITY OF SAMPLES OF GREASE WOOL AND SCOURED WOOL

Samples	Lower channel (net counts/min./lb.)	Upper channel (net counts/min./lb.)
	Mean $\pm$ S.D.	Mean $\pm$ S.D.
Maryland grease wool	690 $\pm$ 111	731 $\pm$ 129
New Mexico grease wool	1,382 $\pm$ 57	669 $\pm$ 101
Idaho grease wool	1,565 $\pm$ 107	929 $\pm$ 76
Idaho scoured wool	46 $\pm$ 12	25 $\pm$ 4

γ -Ray measurements were made with samples of grease wool weighing between 8.6 and 10.0 lb. The grease wool samples were placed for counting in a fibre drum 11½ in. in diameter and 21 in. long. The wool had been sheared in the spring of 1959 from sheep from Maryland, New Mexico and Idaho. The 6 samples of Maryland grease wool were taken from pooled wool, while the 6 samples from the other locations were each taken from individual fleeces. Measurements were also made of 6 scoured wool samples from 1958 Idaho wool. Each of these samples, which weighed between 4.0 and 5.6 lb., was an entire fleece.

The mean values and standard deviations for each group of 6 samples are presented in Table 1. The scoured wool samples emitted a much lower amount of γ -ray radioactivity than did the grease wool samples. Domestic grease wool may contain 25–80 per cent impurities³. The major impurities in grease wool are grease, suint, and dirt. The suint or dried

perspiration is quite high in potassium content. Since all potassium in Nature contains an essentially constant proportion of the γ -ray emitter, potassium-40 (ref. 4), with an energy of 1.46 MeV., it is probable that the upper channel measurements reflect the presence of suint in the grease wool samples. Grease wool may contain 5–40 per cent dirt content³. It will be noted that the lower channel net counts per min. per lb. values for grease wool from the three locations vary more widely than do the upper channel values. Natural radioactivity from soil⁵ as well as fall-out debris may be factors contributing to the lower channel counts.

The γ -ray radioactivity of the clean wool is only a small fraction of that found in grease wool. Thus the bulk of the content of grease wool emitting γ -rays is associated with its impurities. Work is being carried out in our laboratories to determine if γ -ray measurements, which can be made non-destructively in a few minutes, may serve as an index for predicting the percentage of impurities present in grease wool and the relative proportions of the major impurities.

An Effect of Tritiated Thymidine on the Incorporation of Thymidine into Chromosomal Deoxyribonucleic Acid

IN the course of a series of experiments designed to test for possible anomalies in the synthesis and behaviour of chromosomal deoxyribonucleic acid resulting from the use of tritiated thymidine, the possibility arose that the tritiated precursor could interfere with the normal course of synthesis and partition by destroying the integrity of the deoxyribonucleic acid molecule or otherwise modifying the normally operative control mechanisms. This possibility was examined by comparing the incorporation of thymidine labelled with carbon-14 into meristematic cells in the presence and absence of tritiated thymidine.

Vicia faba roots were incubated for a period of 10 hr. in three different media: ¹⁴C-2-thymidine (New England Nuclear Corporation), 2.7 μ C./ μ mole, 1 μ C./ml.; tritiated thymidine (Schwarz Bio Research Inc.), 3,000 μ C./ μ mole, 5 μ C./ml.; ¹⁴C-2-thymidine and

Fig. 1. Diagrammatic illustration of a two-layer stripping film preparation

tritiated thymidine with a final specific activity of 16 $\mu\text{C}/\mu\text{mole}$ and a concentration of 6 $\mu\text{C}/\text{ml}$. The roots were fixed, briefly hydrolysed, squashed and covered with two layers of Kodak AR-10 stripping film (Fig. 1). After 19 days of exposure the autoradiographic preparations were developed and analysed by visual grain counts. The first film layer served as an effective screen against tritium β -particles: relative to the first layer, grain densities in the second layer for carbon-14 were about 50 per cent and for tritium about 0.5 per cent. The second layer over cells labelled with tritium alone showed a grain density over nuclei which was only 2 above background. This number was subtracted from the counts of doubly labelled nuclei in the main analysis which was carried out in the second layer of ^{14}C -thymidine and ^3H -thymidine labelled cells. The results of this analysis are plotted in Fig. 2 and represent pure carbon-14 grain numbers.

These results demonstrate that tritiated thymidine enhances the incorporation of thymidine labelled with carbon-14 and lead to the conclusion that incorporation of tritiated thymidine into deoxyribonucleic acid cannot be assumed to measure normal amounts of synthesis of the acid but does in fact bring about modifications. (The possibility that carbon-14-thymidine itself produces similar difficulties is theoretically less likely, but cannot be easily evaluated in an experiment of this design.)

It is of interest to note in this connexion recent reports of chromosome breakage and reduction in mitotic index¹, increased mutation frequency² (both attributed to tritiated thymidine) and the demonstration of structural modifications in tritiated deoxyribonucleic acid³. These results, together with those presented here, form a broad spectrum of detectable modifications in the deoxyribonucleic acid molecule brought about by the introduction of tritium-labelled components. The finding of Pele and LaCour⁴ of

Fig. 2. The incorporation of thymidine labelled with carbon-14 in the presence and absence of tritiated thymidine

excessive incorporation of tritiated thymidine in cells where similarly extensive incorporation has not been noted with other labelled precursors, and the apparent lack of quantitative correspondence between tritiated thymidine incorporation and cytochemically demonstrable deoxyribonucleic acid increase in puffed regions of polytene chromosomes^{5,6} may also prove to be examples of tritiated thymidine effects rather than evidence for metabolic activity of deoxyribonucleic acid.

The results reported here are not unexpected in view of the extremely high ionization density produced by tritium β -particles and the complex structure of the deoxyribonucleic acid molecule^{7,8}. It is somewhat surprising that a measurable effect is elicited by tritiated thymidine in as low a specific activity as was used in the present experiment (less than 16 $\mu\text{C}/\mu\text{mole}$). The explanation of this circumstance may lie in the sensitivity of the detection system we have employed, that is, the use of a tracer to measure disturbances produced by another.

A discussion of the possible nature of the modifications introduced by tritiated thymidine into chromosomal deoxyribonucleic acid behaviour is in preparation and will be published together with further data on the effect of this precursor on total levels of deoxyribonucleic acid.

Influence of Thyroid on Radiophosphorus Metabolism in Fish

INFORMATION concerning the endocrinological regulation of mineral metabolism in fishes is lacking. The problem is particularly interesting because the parathyroid gland which regulates the normal calcium and phosphorus content within the body in higher vertebrates is supposed to be absent in fishes. I have tried to find out if the thyroid had any control over the mineral metabolism in yearling salmon, *Salmo salar* L.^{1,2}. Since surgical thyroidectomy is not possible in fishes, an attempt was made to destroy the thyroid follicles by anti-thyroid drugs. Successful destruction could not be achieved since the fishes were treated with thiourea for a very short time. The result of the experiments suggested that when fish were treated with thiourea for a short time, thyroid was indirectly stimulated by thyrotropin secreted by the pituitary and so the uptake of phosphorus-32 was more than in the controls; in thyroxine-injected fish the uptake was a maximum because the stimulation was direct.

Complete thyroidectomy has been achieved by repeated injections of radioiodine³. In the present

investigations, goldfish, *Carassius auratus* L., were injected intraperitoneally with 40, 30, 20 and 10 μ c. of iodine-131 respectively for 4 months—one injection every month. Histological examination of the thyroid after this period showed that radioiodine had selectively destroyed all the thyroid follicles. Another group of goldfish were injected with 0.4 ml. of 0.1 per cent thiourea three times a week for 2 weeks. Then for the next 3 weeks the volume of injection was reduced to 0.2 ml. The thyroid in this case became hypertrophied and hyperplastic, with increased number of very small follicles. The height of the cell was greatly increased and the colloid was very scanty. A third group of goldfish was maintained to serve as control. For every injection proper precautions were taken not to disturb the osmotic balance in the fish.

The foregoing groups of fishes were then subjected to three different sets of treatments. Fishes were given three injections of physiological saline, extract of acetone-dried goldfish pituitary gland (to supply them with additional quantity of thyrotropin) and 0.1 per cent L-thyroxine (Nutritional Biochemical Corp.) respectively on alternate days. The volume injected at a time was 0.2 ml. Radiophosphorus was then added to all the aquaria. The antibiotic tetracycline was put in the aquaria to eliminate any bacterial activity. Table 1 shows the amount of radiophosphorus absorbed in various sets.

Table 1. PHOSPHORUS-32 ABSORBED BY THE VARIOUS GROUPS OF FISHES INJECTED WITH PHYSIOLOGICAL SALINE, PITUITARY, AND THYROXINE

	Injections given	Phosphorus-32 absorbed (per cent)
Iodine-131-injected fish	A Physiological saline	22.9
	B Pituitary	24.6
	C Thyroxine	34.6
Thiourea-injected fish	A Physiological saline	26.7
	B Pituitary	37.9
	C Thyroxine	45.9
Controls	A Physiological saline	45.0
	B Pituitary	58.3
	C Thyroxine	66.2

The conclusions drawn from the experiments are that radioiodine completely destroyed the thyroid follicles and so the radiophosphorus uptake was low (22.9 per cent), approximately half that of the controls (45.0 per cent). Injections of pituitary extract did not have much effect (uptake 24.6 per cent). This could be explained by the complete destruction of thyroid; thyrotropin of the pituitary which has the thyroid-stimulating function could not produce any effect. But the injections of the thyroid hormone, thyroxine, increased the uptake from 22.9 to 34.6 per cent (50 per cent increase).

The uptake of radiophosphorus in thiourea-injected fishes (26.7 per cent) resembles that of fishes injected with iodine-131, but the injections of pituitary extract increased the uptake in these fishes from 26.7 to 37.5 per cent (40 per cent increase). This is because the thyroid follicles had only become hypertrophied and hyperplastic and as a result of the loss of colloid they were inactivated. Thyrotropin of the pituitary, therefore, could cause stimulation leading to an increased uptake. When thiourea-treated fish were given thyroxine injections the uptake (45.9 per cent) came to the normal level of controls (45.0 per cent). In the latter, pituitary and thyroxine injections raised the uptake of radiophosphorus from 45.0 to

58.3 and 66.2 per cent respectively. The results show that thyroid has positive influence over the mineral metabolism in fish, but it cannot be said definitely at present whether this control is direct or is indirect through some intermediate agency. Further work is in progress and the detailed report of this work will be published elsewhere.

I am grateful to Prof. F. R. Hayes for his suggestions and encouragement. Thanks are also due to the National Research Council of Canada for the award of a post-doctorate fellowship.

BIOLOGY

Interspecific Differences in Strontium Uptake by Pasture Plants as a Function of Root Cation-Exchange Capacity

Vose and Koontz¹ have reported differences in strontium contents of pasture plants. As there is evidence that the uptake of cations may be influenced by the root cation-exchange capacity of plants²⁻⁴ it was of interest to compare the observed variation in strontium uptake among the plants with the corresponding root cation-exchange capacities.

Root cation-exchange capacity measurements of several of the plants used by Vose and Koontz¹ had previously been made by a method based on that of Drake *et al.*⁵ and these results are shown in Table 1. It must be stressed that these results have only limited application as root cation-exchange capacity has been shown to vary with different levels of nutrition⁶. However, when the level of nutrition is similar for all plants (as was the case in the experiments of Vose and Koontz), then the plants should show much the same relative differences in root cation-exchange capacity. Varietal differences in exchange capacity between the plants tested in New Zealand and those used by Vose and Koontz may also cause some perturbation of the results.

By applying Donnan distribution laws to the root membrane-soil solution-soil colloid system, it may be predicted that the higher the cation-exchange capacity of the root surface, the greater will be the proportion of divalent cations within the root micellar solution⁷. As this initial adsorption on the root surface is the first stage of nutrient absorption by plants and, in dilute solutions, appears to have a considerable effect on the quantity and ratio of ions

Table 1

Plant	Root cation-exchange capacity (m.equiv./100 gm. oven-dry roots)
<i>Bromus inermis</i>	25
<i>Lolium perenne</i>	20
<i>Phleum pratense</i>	23
<i>Phalaris tuberosa</i>	18
<i>Dactylis glomerata</i>	23
<i>Medicago sativa</i>	48
<i>Trifolium repens</i>	42
<i>T. pratense</i>	46
<i>Lotus corniculatus</i>	36

Fig. 1. Strontium uptake (from Vose and Koontz (ref. 1)) as a function of root cation-exchange capacity: $y = 0.091x - 1.01$; $r = 0.91$

absorbed, it would be expected that the uptake of strontium would increase with increase in root cation-exchange capacity. The highly significant correlation between the uptake of strontium recorded by Vose and Koontz¹ and the root cation-exchange capacity (Fig. 1) indicates that the predicted effect of root cation-exchange capacity differences on ion uptake may be a strong factor in determining interspecific differences in uptake of strontium.

The exchange capacity figures used here differ from those obtained by Drake *et al.*². However, the results of these workers significantly correlate with the strontium uptake in a similar manner to those shown here.

While the strontium content varied greatly among species, the calcium to strontium ratio remained constant¹. This lack of discrimination between the two divalent ions by all species is to be expected if it is accepted that exchange reactions on the root surface determine the ratio of ions absorbed by the plants.

A Possible Mechanism of Cell-Wall Formation

GOLDACRE¹ has shown that if a surface film of a lipo-protein on water is compressed, it tends to form folds and ultimately cigar-shaped fibres consisting of a double lipo-protein layer with water inside and outside. It was suggested that such fibres could have been a reaction-space for the original formation of living cells. Danielli² formed double lipo-protein layers by dropping dense protein solution through an oil layer into a less-dense protein solution. In this case, the film was spherical in shape and included a layer of oil. Sigwart and Nassenstein³ have formed

spherical shells of water in benzene by ejecting benzene drops from a nozzle preferentially wetted by water.

I have observed an alternative method of formation of a spherical shell of oil stabilized with protein and separating two aqueous phases. A dilute (0.1 per cent) aqueous solution of bovine plasma albumin is placed in a beaker beneath a layer of petroleum ether (80–100° C.); air is then bubbled into the liquid for a few seconds. Spherical shells of the type formed by Danielli² may be observed afterwards in the water. Their sizes range up to 2–3 mm. Most of the shells rise to the oil-water interface, but some disintegrate, leaving one small oil droplet.

Fig. 1. Formation of a spherical shell

The mechanism of formation of the spherical shell is believed to be the deformation of an oil droplet by an eddy in the way illustrated on Fig. 1. Spherical shells containing air ('inverse bubbles') have been formed in a similar manner⁴. This mechanism of formation of protein-stabilized lipid shells seems to be at least as likely in Nature as those suggested by earlier workers^{1,2}. Given a 'primeval soup' of the right composition, the only physical requirement for the mechanism is turbulence.

Thanks are due to the Department of Scientific and Industrial Research for financial assistance while this work was carried out.

The Intestine in Members of the Genus *Raja* and Host-specificity in the Tetracyllidae

It was recently found that some species of the genus *Raja* could be distinguished solely on differences in the morphology of their spiral valves, in particular, from the form of their mucosae. A brief account of the latter is given here because, so far as I know, these differences have not been described previously. In addition, it is thought that variations of this kind may

Figs. 1-3. Facial sections near the surface of the mucosa and from the middle region of the spiral valve of *Raja*. (1) *Raja montagui*. (2) *Raja clavata*. (3) *Raja naevus*

explain, in part, the high degree of host specificity found in the Tetracanthellidae, and may have a bearing on specificity in other orders of the Cestoda. A more detailed account of the work will be published elsewhere.

A facial section near the surface of the mucosa of *Raja montagui* shows (Fig. 1) that villi are absent. Instead the surface is composed of variously arranged and folded ridges which join to form a complicated network. The spaces between the ridges become progressively shallower and less in volume from the anterior to the posterior region of the intestine. Furthermore, these ridges are not always at the same level and therefore the surface of the mucosa has a corrugated and an irregular appearance. In *Raja clavata*, however, the surface is relatively smooth but composed of a fine regular network of ridges (Fig. 2), the intervening spaces leading into tubular crypts which are deeper in the anterior region. *Raja naevus* can be distinguished from these two species because well-developed villi are present (Fig. 3). *Raja brachyura* possesses a mucosa which at first glance is like that of *Raja montagui*, but the ridges are not identical in their detailed structure. The mucosa of *Raja micro-ocellata* resembles that of *Raja clavata*, but a noticeable difference occurs in the form of the muscular layers in the walls of their intestines.

The above differences may be of value, because it is not always easy to identify species of the genus *Raja* on other characters. Parker¹ described and figured variations in the mucosa of different species and in individuals of the same species of the genus. The specimens of *Raja* that I have examined so far, however, have not revealed a significant variation in different individuals. It is possible, therefore, that Parker was dealing with two species in his account of the mucosa of *Raja montagui*. One of his figures supports this view, as it resembles the mucosa of either the spiral valve of *Raja clavata* or that of *Raja micro-ocellata*. It may have been the former, in view of its abundance at Plymouth and because it can occasionally be confused with *Raja montagui*. On the other hand, the external features of *Raja micro-ocellata* are very distinctive.

The variations found in the intestine of *Raja* are not unlike those previously described in some teleost fishes; and although they suggest that a correlation may occur between feeding habits and the structure of the intestine, the possibility of a direct relationship will require a very careful analysis. Little is known

of the feeding habits of rays, but preliminary observations suggest that some species of *Raja* may be more selective in their feeding habits than hitherto believed. If a correlation between food and the structure of the intestine does occur in this genus, it will obviously have a very important bearing on the specificity of their cestode parasites.

In recent work on the Tetracanthellidae of elasmobranchs caught off the British Isles, I have been able to confirm that host-specificity is very well marked in these cestodes. I stated earlier² that a correlation occurs between the morphology of the intestine in elasmobranchs and the structure of the scolex of their cestodes. It was then suggested that the structure of the gut was a possible factor contributing towards host-specificity in the Tetracanthellidae, and since so little was known of the morphology of the intestine it was decided to investigate this organ in greater detail. It has been confirmed that many genera and species of the Tetracanthellidae, in particular those found in British rays, show a remarkable adaptation to their environment. It is possible that these species can establish themselves successfully in a particular host only if the scolex is suitable for the habitat. This is supported by the literature on the Tetracanthellidae, which suggests that the main features of the scolex are laid down in an early stage of development of the cestode. In addition, preliminary observations on some species of the genus *Echeneibothrium* indicate that young immature individuals possess a scolex which is almost identical in size and structure with that of the adult.

There is also some evidence that the different genera and species of cestodes which are found in the same species of elasmobranch select particular regions of the intestine, and that in many cases different kinds of scolices show a relationship to the depths of the villi, crypts or reticulations of the mucosa as well as to the volume of their intervening spaces.

The above comments are interesting in view of the remarks made by Shulman³ and Llewellyn⁴ on morphological factors affecting the host-specificity of some helminth parasites. The results so far obtained indicate a similar phenomenon in the Tetracanthellidae, but it is assumed that other factors must operate in stimulating these cestodes to settle where optimum conditions occur for protection, nourishment, growth and reproduction. For example, physiological factors, in particular the carbohydrate, fat and protein metabolism of the Tetracanthellidae, are probably very

important for determining their host and habitat specificity.

External Sexual Differences and their Significance in *Mormyrus kannume* Forskal. 1775

Mormyrus kannume is distributed in the Nile system from the five major lakes of Uganda to the delta, and probably also in the Athi River system in Kenya¹. The present communication was compiled from observations on specimens from the shallow waters of northern Lake Victoria.

There are external sexual differences in *M. kannume*. The base of the anal fin of the female is inclined at an angle of between 17 and 28° to an arbitrary axis between eye and tail fork, whereas in the male this angle lies between 32 and 33°. In the female or immature male, the anal fin is angular in outline, and the slender rays diverge from the base to the periphery of the fin. The anal fin of the mature male is rounded in outline, and the thickened, tapered rays converge to the periphery from the fin base, and due to the constriction at the periphery, when the fin is spread, a depression appears in the centre. Every immature male has an anal fin similar to that of a female, except for the angle at which it is attached to the body. As the testis ripens, the anal fin becomes modified to the form found in the mature male, and after breeding, the testis regresses and the anal fin gradually assumes its original form.

The significance of the modified anal fin cannot be conclusively demonstrated, since the breeding behaviour of *M. kannume* has not been observed. The simultaneous maturation of the gonad and modification of the anal fin in the male, however, indicate that the anal fin has an important function during breeding. If recently killed male and female are placed side by side with their anal fins spread and in contact at the peripheries, a chamber is formed between their anal fins in the manner illustrated in Fig. 1. If this chamber is used to surround the eggs

during fertilization, fewer spermatazoa might need to be produced than if the gametes were dissipated into the surrounding water before fertilization. Therefore the use of a fertilization chamber in *M. kannume* during spawning might account for the relatively minute testis of the mature male. In every mature male fish with a total weight of less than 600 gm., the testis never weighed more than 3 gm., and a specimen weighing more than 4 kgm. had a ripe testis which weighed only 7 gm. In a variety of experiments in which macerated testis material and eggs taken from ovulated ovaries were mixed in small volumes of water, effective fertilization was never more than 25 per cent, and frequently less than 10 per cent. This may indicate that the gametes of this species are viable for only a limited period after contact with water, and that fertilization is possible only where immediate intimacy between ovum and sperm occurs. Immediate contact between ovum and sperm may be possible within the fertilization chamber.

M. kannume is a very active gregarious species which probably has the co-ordinative ability to form a fertilization chamber. I have observed that, after being frightened, individuals of *Marcusenius nigricans*, another very active gregarious Mormyrid, form an unusually compact shoal which swims as a single unit through rocky crevices. Individuals of *M. kannume* may also be able to maintain close contact with each other while swimming, and as an extension of this type of behaviour, pairs may be able to form a fertilization chamber during spawning.

Isolation of Liver Nuclei

A METHOD of isolating pure nuclei from rat liver has been elaborated from those described by Alfrey¹, Schneider and Hogeboom², Chauveau³ and Zbarskij⁴.

A rat was fasted for 24 hr. and then killed by decapitation. The liver was perfused with 0.25 M saccharose containing 0.0018 M calcium chloride and homogenized in a Teflon Potter-Elvehjem homogenizer for 2-3 min. at 1,000 r.p.m. in 0.25 M saccharose (+ 0.0018 M calcium chloride) at 1:10 dilution. The homogenate was filtered through four sheets of cotton gauze or through Jena G O glass filter. The filtrate was afterwards centrifuged for 5 min. at 500 r.p.m. in the horizontal head at 0-2° C. Thereafter we pipetted out the supernatant, which was not sharply separated from the precipitate, and put it on the surface of 0.34 M saccharose (+ 0.0018 M calcium chloride) and then centrifuged for 10 min. at 2,000 r.p.m. and 0-2° C. in the horizontal head. The supernatant was rejected and the precipitate, composed mainly of nuclei, was resuspended in 0.25 saccharose (+ 0.0018 M calcium chloride) and again put on the surface of 2.2 M saccharose, the density of which was exactly 1.272 gm./ml. This density, according to Zbarskij⁴, allows the sedimentation of pure nuclei only, and at the same time it prevents the sedimentation of smaller cellular structures and of whole cells.

Fig. 1. Diagrammatic transverse section of a pair of fish in lateral contact in the region of their anal fins. (X $\frac{1}{2}$). W, Depression in centre of male anal fin; X, mature male (34 cm.); Y, female (33 cm.); Z, extruded ova within the fertilization chamber

The distance from phase border, that is, from the boundary layer, of 2.2 M saccharose and 0.25 M saccharose with suspended nuclei to the bottom of tube was 1.5 cm., and the time of centrifuging was 30 min. at 30,000g (as calculated for the bottom of tube). The diameter of the tube was 16 mm. The last centrifuging was performed on a super-speed attachment of an MSE refrigerator centrifuge at 0-2° C. The nuclear fraction appears as a light yellow precipitate. When this method is used special attention must be paid in order to attain suitable thickness of the layer of 2.2 M saccharose solution and also to the diameter of the tube.

The smear of the nuclear fraction suspended in 0.25 M saccharose showed no whole cells, and only few very small fragments of cells were observed. The appearance of the nuclei was like this in living cells. The nuclei have clearly visible nucleoli and normally distributed intranuclear constituents; this is evidence of their normal status. We did not observe any deformation or agglutination of nuclei prepared by this method.

Case of Apparent Resistance of *Rattus norvegicus* Berkenhout to Anticoagulant Poisons

OVER a period of two months, a heavy rat population on a farm in the west of Scotland was treated with two anticoagulant poisons, 'Diphacinone' and 'Warfarin'. Although the treatments were properly conducted, and the rats ate the poison bait freely, little impression was made on the size of the population. There was no evidence of recruitment from outside, and the conclusion drawn was that this population was more than normally resistant to these anticoagulants. Cage tests on 28 animals trapped on the farm to confirm this gave the results shown in Table 1.

Table 1

	Poison	Concentration (per cent)	No. of days feeding	Mortality
Farm rats	'Diphacinone'	0.0025	5	2/9
	'Warfarin'	0.005	5	1/9
	Nil	—	—	0/10
Controls	'Warfarin'	0.005	5	12/15

The remaining 25 rats were further tested at the Ministry of Agriculture, Fisheries and Food laboratories at Tolworth with similar results. More work on the survivors and their progeny is in progress.

Ophiuroids feeding on Phytoplankton

RECENTLY, Nagabhushanam and Colman¹ have described carrion-eating by some species of ophiuroids including *Ophiocomina nigra* (Abild.) and *Ophiothrix fragilis* (Abild.), from observations both in the laboratory and in the sea, a phenomenon which has been recorded previously^{2,3}. The two species mentioned as well as *Ophiopholis aculeata* (L.) have, however, been reported to feed on a wide range of food from seston and plankton to bottom invertebrates^{2,3}. In particular, *Ophiothrix fragilis* and *Ophiopholis aculeata* are considered to be mainly suspension feeders^{4,5} (using strong ciliary currents⁶ in catching detritus), being also facultatively carnivorous. Of the species mentioned, *Ophiocomina* is anatomically well adapted for a carnivorous habit³. Nevertheless, all the species mentioned are considered to feed in essentially the same way^{2,3}.

In order to evaluate the efficiency as suspension feeders of the three species mentioned, we have fed them with phytoplankton labelled with carbon-14. The animals were starved for 1-2 weeks. Two or three individuals of the same species were placed in each of a series of jars containing 400 ml. membrane-filtered sea water to which identical concentrations of carbon-14 labelled plankton algae (natural phytoplankton populations) were added. In every experiment mentioned, constant stirring in 'plunger jars' prevented settling of phytoplankton. The animals were kept in the dark and at a constant temperature.

Two different substrata for the ophiuroids were used; stones and empty shells as one, and the octocoral *Alcyonium digitatum* L. as the other. The latter was used because *Ophiothrix* is often found clinging to it, a phenomenon which is in accordance with the view that *Ophiothrix* is a reophile animal⁸. After 18 hr. the radioactivity of the stomach contents of the ophiuroids was measured.

Table 1. RADIOACTIVITY (c./min.) OF STOMACH CONTENTS OF OPHIUROIDS AND TISSUE HOMOGENATE OF *Alcyonium*

Species	Substratum	
	Stones and empty shells (c./min.)	<i>Alcyonium digitatum</i> (c./min.)
<i>Ophiothrix</i>	186	326
	226	120
<i>Ophiopholis</i>	57	5.5
	162	59
	79	20.3
<i>Ophiocomina</i>	0	0
	0	0.9
	0	1.3
<i>Alcyonium</i>	—	110

On the dead substrates, no uptake of phytoplankton by *Ophiocomina* was found. The faint traces of radioactivity measured in specimens of *Ophiocomina* using *Alcyonium* as a substrate is a secondary phenomenon as the octocoral has *a priori* filtered the algae. *Ophiocomina* accordingly cannot be regarded as a suspension feeder, in contrast to the two other species which are extremely efficient suspension feeders, *Ophiothrix* being the superior one.

To measure the rate of removal of plankton algae by starved *Ophiothrix* and *Ophiopholis*, these species were fed with carbon-14 labelled strains of *Skeletonema costatum*. In both species three different concentrations of *Skeletonema* were used (10:5:1), but the starting activity in the same concentrations was identical. In each of the 2 x 3 jars, three animals were placed in 400 ml. membrane-filtered sea water. The radioactivity in subsamples of 10 ml. water was measured at increasing time-intervals starting with 1 hr.

SOIL SCIENCE

Changes with Time in the Availability of Strontium-90 in Soil

Fig. 1. Curves: Relative decrease in concentration of *Sceletonema* caused by filtration of *Ophiopholis aculeata* and *Ophiopholis aculeata*. Columns: Relative rate of removal per hr. of *Sceletonema* by *Ophiopholis aculeata*.

As the feeding-rates (relative) of the ophiuroids in the three concentrations of algae were almost of the same order of size, the relative average rate of removal of algae is shown in Fig. 1.

Obviously due to hunger, the filtering-rate is always greatest during the first hour and of about the same intensity in both *Ophiopholis* and *Ophiopholis* (respectively 37 per cent and 34 per cent of the algae present were removed). After 4 hr., however, *Ophiopholis* had surpassed *Ophiopholis*, and after 23 hr. *Ophiopholis* had removed 88 per cent of the algae, *Ophiopholis* only 75 per cent.

In all our experiments *Ophiopholis* has proved to be the most efficient filterer of phytoplankton. The highest efficiency was found in three specimens which removed about 50 per cent of the *Sceletonema* present in 400 ml. sea water in 1 hr. This ability probably explains the mass occurrences of this species (> 340 individuals per m.²) in the English Channel⁵, where strong tidal currents carry considerable amounts of suspended matter over the food-collecting net of tangled *Ophiopholis* arms. Our demonstration of the absence of filtering in *Ophiocomina nigra* also helps to explain the low ratio of only about 0.6 of this species for every 100 *Ophiopholis fragilis* in the English Channel⁶.

DETAILED knowledge of the behaviour of strontium-90 in soil is of particular importance in assessing the long-term consequences of its deposition on agricultural land. Experiments have been carried out to determine whether strontium-90 becomes progressively fixed and therefore less available to plants. The majority of the more recent evidence suggests that the availability is decreased to only a small extent, if at all, by changes in the physico-chemical state of strontium-90 in the soil¹. Deeper penetration through the soil or a more thorough mixing may, however, reduce the quantity of strontium-90 which is absorbed by plants².

Further information on this subject is being obtained from a long-term experiment now in progress in this laboratory. The experiment was designed to investigate both the rate at which strontium-90 moves down the soil profile under natural conditions and the manner in which the absorption of strontium-90 by plants changes with time, either as a result of penetration in the soil or because of chemical changes over long periods. Concrete cylinders, 1 yd. wide and 1 yd. deep, were filled with five different soils (Table 1) and left in the open to consolidate for nine months. In the summer of 1956, 1 mc. of carrier-free strontium-90 in aqueous solution was applied to the surface soil of each. Some cylinders were left bare and others were planted with rye grass which was sampled and assayed at regular intervals. In the four seasons for which results are now available, the ratio of strontium-90 to calcium in the grass grown on all soils has decreased by some 20–30 per cent. This reduction could be attributed to either or both of the causes; namely, to slow chemical changes which have reduced the availability of strontium-90 in the soil or to the increasing penetration of strontium-90 down the soil profile. The work here described was undertaken to obtain more direct information on possible changes with time in the physico-chemical form of strontium-90 in the soil; the manner in which it is redistributed down the soil profile will be described elsewhere.

Table 1. DATA ON SOILS

Soil	pH	Total exchange capacity m.equiv./100 gm.	Exchangeable calcium
I	6.4	10.2	5.1
II	6.7	10.4	6.3
III	5.7	12.2	6.6
IV	7.6	26.2	23.1
V	7.8	28.7	28.0

It is known that chemical extraction procedures do not necessarily give adequate information on the relative availability to plants of strontium and calcium in the soil; difficulties arise owing to the fact that the chemical composition of the soil is to a greater or lesser extent modified by such treatments. An improved procedure which depends on measuring the relative concentration (or potential) of the two ions in a solution with which the soil is in true equilibrium was devised by Schofield and preliminary results have been published³. The same principle can be used to compare the availability of strontium ions which have been present in a soil for different periods of time. Dilute calcium chloride solution (0.01 M) has been found a suitable medium in which to equilibrate

soil for this purpose; changes in the availability of strontium can be inferred from the relative extent to which material which has been present in the soil for different periods passes into this solution.

This method has been used to compare the availability of the strontium-90 which had been incorporated in the soils for $3\frac{1}{2}$ years, from the cylinders referred to above, with that of strontium-89 which was freshly added to the soil. Small aliquots of air-dry soil from the experimental cylinders were moistened with water or with a solution of carrier-free strontium-89. Seven days later they were shaken for 24 hr. with 0.01 M calcium chloride solution (soil/solution ratio of 1:8); three replicates of each treatment were employed. After centrifuging, the clear supernatant solutions were decanted and the quantities of strontium-89 or -90 which had passed into solution were determined. The soils were then boiled with 8 M nitric acid for 5 min. Repeated extractions with hot concentrated acid were carried out on some samples. The residual activity in the soil was determined with a calibrated beta scintillation counter; it was ascertained that the strontium-89 extracted from the soil, together with that estimated as remaining therein, did not differ significantly from that originally added.

The results in Table 2 show that the amount of freshly added strontium-89 which became equilibrated with the calcium chloride solution ranged from 55.5 per cent in soil I to 26.5 per cent in soil IV. The corresponding values for strontium-90, which had been in the soil for $3\frac{1}{2}$ years, were some 10-3 per cent lower. This difference was significant ($P > 0.01$) for all soils except soil V. The nitric acid extraction removed almost all the strontium-89 from the soils but about 1 per cent of the strontium-90 remained. Even after repeated extractions with concentrated acid, the amount of strontium-90 remaining in the soil was not greatly reduced.

Table 2. THE EXTRACTION OF FRESHLY ADDED STRONTIUM-89, OR STRONTIUM-90 WHICH HAD BEEN PRESENT FOR $3\frac{1}{2}$ YEARS, FROM VARIOUS SOILS

Soil	I	I+Ca*	II	III	IV	V
% removed from the soil by equilibration with 0.01 M calcium chloride solution						
⁸⁹ Sr	55.5	46.3	49.1	49.9	26.5	27.9
⁹⁰ Sr	50.7	41.7	44.7	45.6	24.5	27.2
⁹⁰ Sr/ ⁸⁹ Sr	0.91	0.90	0.91	0.91	0.92	0.97
% which remained in the soil after boiling for 5 min. with 8 M nitric acid						
⁸⁹ Sr	0.05	—	0.06	0.10	0.05	0.30
⁹⁰ Sr	1.6	1.4	1.0	1.8	1.5	0.9
⁹⁰ Sr/ ⁸⁹ Sr	32	—	17	18	30	3
% which remained in the soil after repeated extractions with nitric acid						
⁸⁹ Sr	0.03	—	0.01	0.03	0.03	0.01
⁹⁰ Sr	1.2	1.0	0.5	1.1	0.6	0.3
⁹⁰ Sr/ ⁸⁹ Sr	40	—	50	37	20	30

* Lime (at the rate of 10 tons/acre) was applied to the soil surface 1 year after the strontium-90.

The result of equilibrating the soils with dilute calcium chloride solution suggests that the availability of the strontium-90 has been reduced by a small amount over the period of $3\frac{1}{2}$ years. Further evidence that some strontium is slowly converted into less-accessible forms is provided by the fact that rigorous extraction with acid displaced less of the strontium-90 which had been present for $3\frac{1}{2}$ years than of the recently added strontium-89.

The mechanism whereby tracer amounts of strontium become firmly bound in soils is of theoretical interest, although these results suggest that the effect

of such physico-chemical changes on the absorption of strontium-90 by plants is too small to be of great significance in the assessment of the passage of strontium-90 through food chains. The present experiment will be repeated after the strontium-90 has been in the soils for a longer period.

I am indebted to the late Dr. R. K. Schofield for his advice during the progress of this work.

VIROLOGY

Mechanical Transmission of the Infectious Variegation Virus of Citrus

INFECTIOUS variegation was described as a possible virus disease of citrus in 1931 by Petri¹. His description of symptoms and his illustrations are similar to those reported by Fawcett and Klotz², who transmitted the causal agent by bud-grafting from variegated lemon to sour orange. They noticed that some of the symptoms were similar to those associated with psorosis and suggested that the diseases might possibly be related. Klotz and Fawcett³ noted that crinkly leaf of lemon is sometimes associated with infectious variegation. Fawcett and Bitancourt⁴ were uncertain whether infectious variegation differed sufficiently from crinkly leaf to be considered a separate disease. From cross-protection studies, Wallace⁵ concluded that infectious variegation is caused by a strain of the psorosis virus. Grant and Smith⁶ reported infectious variegation in Florida and transmitted the causal agent by bud and leaf-pie grafts to several different species of citrus.

Many unsuccessful attempts have been made to transmit mechanically the viruses responsible for tristeza, psorosis, xyloporosis, and exocortis. To date these failures have been explained on the basis of insufficient virus concentration in the inocula, inhibitors, intrinsic properties of the virus, or the susceptibility of the test plant. In 1959, Holmes⁷ reported the mechanical transmission of potato mottle virus to three species of citrus. The virus induced only one local lesion on one plant of each species, and was recovered to plants of *Nicotiana tabacum*. The virus was not recovered from non-inoculated leaves of citrus. Holmes⁷ concluded that failures to transmit citrus viruses mechanically may have been due to the use of insusceptible or insufficiently susceptible test plants rather than to the presence of inhibitors in citrus foliage.

In the present investigations, leaves of Eureka lemon plants with typical symptoms of infectious variegation—such as vein banding, veinlet banding, speckle, blotch, and crinkle—were frozen (-10° to -20° C.) in a mortar with 1 ml. of 20 per cent sucrose

per gm. of leaf material and with a small amount of activated charcoal. The material was thawed and triturated with a mortar and pestle. The pulp was squeezed through cheese-cloth, and expressed juice obtained in this way was used for subsequent inoculations. Leaves to be inoculated were dusted with 500-mesh 'Carborundum' and inoculated by rubbing with a gauze pad saturated with inoculum or by brushing with a nylon-bristle brush that had been dipped in the inoculum. Inoculated leaves were rinsed with tap water immediately after inoculation. The tests were conducted during January-March. The test plants were either very young seedlings (2- to 4-leaf stage) or older seedlings approximately 12-14 in. high. Controls were comparable test plants that were treated as described except that leaves from healthy Eureka lemon plants provided the source of 'inoculum'.

Table 1. NUMBERS OF CITRUS SEEDLINGS INFECTED BY INFECTIOUS VARIATION VIRUS MECHANICALLY TRANSMITTED FROM EUREKA LEMON

Exp.	Test species	Relative age of test plants	Transmission	
			Test plants*	Controls
1	Eureka lemon	Young†	7/7	0/7
2	Eureka lemon	Young	5/5	0/5
3	Sour orange	Young	5/5	0/5
4	Eureka lemon	Old‡	3/3	0/3
5	Eureka lemon	Old	0/3	0/3
6	Sour orange	Old	1/3	0/3

* Numerator is number of plants infected after a five-week period and the denominator the number inoculated.

† Seedlings in 2- to 4-leaf stage.

‡ Seedlings 12-14 in. tall.

In three experiments in which the test plants were young when mechanically inoculated, all inoculated plants became infected (Table 1). Some transmission to older plants was obtained, but the results were erratic. Fifteen to twenty-five days after inoculation, some Eureka lemon plants exhibited systemic symptoms identical with those on the source plant. The sour-orange seedlings exhibited vein banding and, later, chlorotic blotches in young leaves, and leaf crinkle and cupping. Some inoculated leaves of Eureka lemon 8-10 days after inoculation exhibited slight chlorotic blotches that afterwards enlarged. When such leaves were cleared in alcohol and stained with iodine, they showed typical starch lesions⁴ (Fig. 1).

Both inoculated and non-inoculated leaves of the test plants were examined for virus in two ways. Mechanical inoculations were attempted by the methods described, and leaf pieces were grafted to lemon and sour-orange seedlings. Virus was recovered from young systemically infected leaves as well as from inoculated leaves of experimentally infected plants by leaf piece-graft inoculations. Virus was transmitted by mechanical means from young systemically infected leaves but not from inoculated leaves. The failure to recover the virus by mechanical means from the inoculated leaves may be due to the age of leaf or to low concentration of virus. Old leaves are difficult to triturate with a mortar and pestle, and the virus concentration may be low because of the type of local virus multiplication.

It seems unlikely that use of insufficiently susceptible test plants could account for the previous failures of mechanical transmission of citrus viruses. The results reported here show that the failure of mechanical transmission of at least one citrus virus is not due to low concentration or intrinsic nature of

Fig. 1. Leaf of Eureka lemon 14 days after mechanical inoculation with infectious variegation virus, showing expansion of initial local lesions and starch-retention pattern. Leaf was cleared in alcohol and stained with iodine

the virus. Earlier attempts may have failed because inhibitors were not removed.

The effect of sucrose and activated charcoal on the successful transmission of infectious variegation from citrus to citrus is unknown. Possibly enzyme-inhibiting properties of sucrose are somehow related to a mechanism by which sucrose might negate the effects of viral inhibitors in juice of citrus leaves. Moreover, viral inhibitors may be adsorbed by the activated charcoal, thus reducing their interference with infection and multiplication.

The beneficial effects of sucrose and activated charcoal may be elucidated after further study. The important fact at present is that a citrus virus has for the first time been transmitted mechanically from citrus to citrus. Mechanical transmission of any citrus virus immediately facilitates work on the properties of the virus, host-range, test plants, symptomatology, purification, serology, indexing methods, and eventually morphology of the virus particle associated with the disease. Further work on mechanical transmission of variegation and other citrus viruses from the point of view of inhibitors, hosts, and virus concentration is in progress.

FORTHCOMING EVENTS

(Meetings marked with an asterisk * are open to the public)

Monday, November 7

BRITISH SOCIETY FOR THE PHILOSOPHY OF SCIENCE (in the Joint Staff Common Room, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. S. Vajda: "The Building of Models and the Theory of Games".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "The Impact of Television on Society" opened by Lord James of Rushmore.

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Miss M. V. Griffith: "The Heat Pump in Great Britain".

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. W. Idris Jones: "The Future of Chemicals from Coal".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (joint meeting with the WOOLWICH POLYTECHNIC SCIENTIFIC SOCIETY, at the Woolwich Polytechnic, Thomas Street, London, S.E.18), at 7 p.m.—Dr. W. Davies: "Some Aspects of the Chemistry of Cancer".

ROYAL GEOGRAPHICAL SOCIETY (joint meeting with the BRITISH SCHOOL OF ARCHAEOLOGY IN IRAQ, at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Prof. M. B. L. Mallowan: "Discoveries at Ur".

Monday, November 7—Tuesday, November 22

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, MEDICAL GROUP (at 16 Princes Gate, London, S.W.7)—Exhibition of Medical Photography.

Tuesday, November 8

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Mr. B. C. Brookes: "A Philosophy of Applied Science".*

INSTITUTION OF MECHANICAL ENGINEERS, AUTOMOBILE DIVISION (at 1 Birdcage Walk, Westminster, London, S.W.1), at 4.30 p.m.—Dr. A. E. W. Austen, Mr. B. E. Knight, Dr. W. T. Lyn and Dr. T. Priode: "Fuel Injection, Combustion and Noise".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF CHEMICAL ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. W. D. Armstrong and Mr. R. M. Wood: "The Dynamic Response of a Distillation Column".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 11, House of Commons, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Recent Developments and Problems Connected with Supersonic Flight" initiated by Mr. P. A. Hufon and Dr. A. B. Russell, C.B.E.

UNIVERSITY OF LONDON (at Senate House, London, W.C.1), at 5.30 p.m.—Prof. M. G. Kendall: "New Prospects in Economic Analysis" (Stamp Memorial Lecture).*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. W. M. Court Brown: "Chromosome Analysis and Clinical Medicine".* (Sixth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

ILLUMINATING ENGINEERING SOCIETY (at the Federation of British Industries, Tothill Street, London, S.W.1), at 6 p.m.—Mr. F. P. Henthorn: "25 Years of Stage Lighting".

INSTITUTION OF THE RUBBER INDUSTRY (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 5.30 p.m.—Mr. P. B. Lindley: "Rubber in Engineering". 7 p.m.—Dr. A. N. Gent and Mr. M. Braden: "Mechanics of Attack of Rubber by Ozone".

ROYAL SOCIETY OF MEDICINE, PSYCHIATRY SECTION (at 1 Wimpole Street, London, W.1), at 8 p.m.—Discussion on "The Use of Psychiatric Skills in Industrial Organizations". Opening Speakers: Dr. J. J. O'Dwyer and Dr. Elliott Jaques.

Wednesday, November 9

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 10.30 a.m.—Symposium on "Vertebrate Locomotion".

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. P. J. Rendle: "Regulation of Carbohydrate Metabolism by Hormones and Other Factors".*

INSTITUTE OF PHYSICS AND THE PHYSICAL SOCIETY, COLOUR GROUP (in Lecture Theatre No. 3, Physics Department, Imperial College, London, S.W.7), at 3 p.m.—Mr. L. B. Happe: "Some Problems of Colour Reproduction in the Cinema"; Mr. J. Vickers: "Problems in Printing Colour Negatives".

PALAEONTOLOGICAL ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Prof. Dorothy Hill (University of Queensland): "The Fine Structure of the Coral Skeleton and its Application in Classification".

UNIVERSITY OF LONDON (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Dr. H. E. Rose: "Vibration Mills and Vibration Milling".* (First of three lectures. Further lectures on November 18 and 23).

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. Charles Wilcocks: "Aspects of Medical Investigation in Africa—Trypanosomiasis".* (Third of four Heath Clark Lectures. Further lecture on November 10.)

ROYAL INSTITUTE OF CHEMISTRY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 5.45 p.m.—Dr. T. C. Waddington: "Liquid Hydrogen Halides as Ionizing Solvents" (Meldola Medal Lecture).

INSTITUTE OF INFORMATION SCIENTISTS (at the College of Preceptors, 2 Bloomsbury Square, London, W.C.1), at 6.15 p.m.—Mr. C. A. Ronan: "Problems in Transliteration of Cyrillic".*

BRITISH INSTITUTION OF RADIO ENGINEERS, MEDICAL AND BIOLOGICAL ELECTRONICS GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. T. G. Brown: "Diagnostic Applications of Ultrasonics".

SOCIETY OF CHEMICAL INDUSTRY, FOOD GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Meeting on "Food Technology in Italy". Speakers: Mr. A. B. Billington, Mr. R. D. Mason, Dr. J. R. Nicholls and Dr. J. Tramer.

SOCIETY FOR PSYCHOLOGICAL RESEARCH (at Kensington Town Hall, Kensington High Street, London, W.8), at 7 p.m.—Mr. Christopher Scott: "The Douglas Johnson T.V. Sitting".

WOMEN'S ENGINEERING SOCIETY (at "Hope House", 45 Great Peter Street, Westminster, London, S.W.1), at 7 p.m.—Mr. E. C. Cookson and Mr. A. H. Emerson: "Railway Modernization and Electrification".

Thursday, November 10

LINKMAN SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. A. Bogdan: "Grass Pollination by Bees in Kenya"; Dr. J. B. Free: "The Pollination of Fruit Trees by Honeybees".

INSTITUTION OF ELECTRICAL ENGINEERS, UTILIZATION SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Prof. F. O. Williams, F.R.S., Dr. E. R. Laithwaite, Mr. J. F. Eastham and Mr. L. S. Pigott: "The Logmotor—a Cylindrical Brushless Variable-Speed Induction Motor"; Prof. F. O. Williams, F.R.S., Dr. E. R. Laithwaite, Mr. J. F. Eastham and Mr. W. Farrer: "Brushless Variable-Speed Induction Motors using Phase-Shift Control".

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. M. R. Pollock: "Physiological Adaptation in Micro-organisms".* (Seventh of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

OIL AND COLOUR CHEMISTS' ASSOCIATION (at the Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London, W.1), at 7 p.m.—Mr. A. G. North: "Water-Thinnable Stoving Finishes".

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 7.30 p.m.—Prof. R. S. Nyholm, F.R.S.: "Electron Configuration and Structure of Transition-metal Complexes" (Tilden Lecture).

RADAR AND ELECTRONICS ASSOCIATION (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 7.30 p.m.—Mr. C. A. Burgess: "V.H.F. Aerial Techniques".*

ROYAL INSTITUTE OF CHEMISTRY (at Croydon Technical College, Fairfield, Croydon), at 7.30 p.m.—Dr. H. J. Barber: "Some Aspects of Chemotherapy".

Thursday, November 10—Friday, November 11

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 10.30 a.m. daily—Discussion on "Progress and Needs of Marine Science" led by Dr. G. E. R. Deacon, F.R.S., and Dr. F. S. Russell, F.R.S.

Friday, November 11

ASSOCIATION OF APPLIED BIOLOGISTS (at the British Museum (Natural History), South Kensington, London, S.W.7), at 10.50 a.m.—Meeting on "Applications of Radiation in Biology".

INSTITUTION OF ELECTRICAL ENGINEERS (joint meeting with the Royal Aeronautical Society, at Savoy Place, London, W.C.2), at 5.30 p.m.—The Rt. Hon. The Viscount Caldecote, D.S.C.: "The Future of 'Electrics' and 'Electronics' in Aircraft and Guided Missiles".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. R. J. Harrison: "Experiments with Diving Seals".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

LECTURER or ASSISTANT LECTURER (preferably with experience in chemical or biochemical aspects of pharmacology) IN THE DEPARTMENT OF PHARMACOLOGY—The Registrar, The University, Leeds 2 (November 14).

BIOCHEMIST (honours graduate with some research experience), to assist Dr. R. M. O. Dawson on isotopic studies on lipid metabolism in rumen micro-organisms and in the ruminant digestive tract—The Secretary, Institute of Animal Physiology, Babraham, Cambridge (November 15).

FISHERIES ADVISER (with a university degree in biology and a minimum of five years experience on both research and development) in the Ministry of Animal Resources, Sudan, for duties which will include the biological and technological investigations leading to the establishment of a profitable inland fisheries industry, and also the training of Sudanese assistants—The Appointments Secretary, Sudan Embassy, 3 Cleveland Row, St. James's, London, S.W.1 (November 15).

LECTURER IN THEORETICAL PHYSICS—Prof. A. Salam, Physics Department, Imperial College of Science and Technology, London, S.W.7 (November 15).

ASSISTANT EXPERIMENTAL OFFICER (with a degree or equivalent qualifications in chemistry) in the DEPARTMENT OF PEDOLOGY, for duties mainly concerned with the chemical analysis of peat and herbage—The Secretary, The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (November 19).

RESEARCH ASSISTANT (graduate in medicine, and preferably some physiological knowledge and experience in simpler biochemical estimations) in the DEPARTMENT OF ANAESTHETICS—The Registrar, King's College (University of Durham), Newcastle upon Tyne (November 19).

READER (with high academic qualifications and good experience in teaching and research) in CIVIL ENGINEERING—The Clerk to the Governing Body, Battersea College of Technology, London, S.W.11 (November 28).

CHAIR OF PURE MATHEMATICS—The Registrar, University College, Singleton Park, Swansea (November 30).

LECTURER IN EDUCATION at the University of New England, Armidale, N.S.W., Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, November 30).

LECTURER IN THE DEPARTMENT OF STATISTICS, University of the Witwatersrand, Johannesburg, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, November 30).

LIBRARIAN—The Secretary, The Queen's University, Belfast (November 30).

RESEARCH FELLOW IN BOTANY at the University College of Rhodesia and Nyasaland for research into the autecology of *Salvinia auriculata*, to be conducted partly at Lake Kariba and partly at the College—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (November 30).

SENIOR LECTURER or LECTURER IN CHEMICAL ENGINEERING at the University of Natal, Durban—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, November 30).

SENIOR LECTURER or LECTURER IN MECHANICAL ENGINEERING at the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (New Zealand and London, November 30).

UNIVERSITY LIBRARIAN—The Registrar, The University, Leicester (November 30).

LECTURER (with an honours degree and preferably some operating or research experience in some aspect of mining engineering) in MINING ENGINEERING in the School of Mining Engineering and Applied Geology, University of New South Wales, Kensington, N.S.W.—The Agent-General for New South Wales, 56-57 Strand, London, W.C.2 (Australia and London, December 2).

LECTURER IN ORGANIC CHEMISTRY at Makerere College (The University College of East Africa)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 10).

CHAIR OF PURE MATHEMATICS—The Registrar, University College of Wales, Aberystwyth (December 31).

PIG INDUSTRY DEVELOPMENT AUTHORITY FELLOW, for research in pig health—The Secretary, Royal College of Veterinary Surgeons Trust, 9 Red Lion Square, London, W.C.1 (February 25).

ASSISTANT, Grade B (with an honours degree in physics, and research or industrial experience in some branch of applied physics), in the DEPARTMENT OF PHYSICS—The Registrar, Bristol College of Science and Technology, Ashley Down, Bristol 7.

CHEMIST (with a first- or good second-class honours degree in chemistry or an equivalent qualification, and preferably experience in the inorganic analytical field and a knowledge of geochemical techniques) in Nyasaland, to take charge of the Geological Survey Departments, chemical laboratory, and to undertake assaying and chemical testing of rocks, including full silicate rock analyses—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.105/4/04.

CHEMIST (with an honours degree in chemistry, veterinary/agricultural or medical experience, and some experience in biochemistry) with the Government of Tanganyika, to supervise the Chemical Section of the Veterinary Research Laboratory (duties will include frequent safaris for experiments in the field)—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.83/8/020.

LECTURER (graduate in physics, preferably with teaching and research experience); and an **ASSISTANT LECTURER** (preferably with teaching or industrial experience) in PHYSICS—The Principal, National College of Food Technology, St. George's Avenue, Weybridge, Surrey.

LECTURER IN PSYCHOLOGY—The Principal, West End Hospital Speech Therapy Training School, 69 Portland Place, London, W.1.

OFFICIAL FELLOW and TUTOR (preferably with interests in pure mathematics) in MATHEMATICS—The College Secretary, Balliol College, Oxford.

RESEARCH ASSISTANT (with a first- or second-class honours degree in mathematics or science) in the SUB-DEPARTMENT OF COMPUTATION, for duties which will include the preparation of programmes for the Ferranti "Pegasus" computer, and the provision of assistance to other users of the machine—The Registrar, The University, Southampton.

TECHNICIAN (with experience of microbiological techniques and preferably some knowledge of biochemical or brewing procedures),

to take charge of large-scale growth of micro-organisms by continuous fermentation methods and to be concerned with growth and purification of bacterial viruses—The Deputy Director, Medical Research Council Biophysics Research Unit, King's College, Strand, London, W.C.2.

WHOLE-TIME BIOCHEMIST (non-resident), for hospital biochemical work in the Mansfield Area Pathology Service—The Hospital Secretary, King's Mill Hospital, Sutton-in-Ashfield, Nottingham.

A COMMONWEALTH ADVISORY AND TECHNICAL SERVICE

THE fourth report of the Select Committee on Estimates for the session 1959-60, which deals with the Colonial Office, is of considerable interest to many scientists and technologists for its section dealing with the Overseas Civil Service*. Of equal scientific interest, however, is the section which examines generally the provision of aid and advice on administrative and technical problems to dependent territories and independent countries in the Commonwealth, and which leads the Select Committee to recommend that a committee of inquiry be set up to consider the establishment of a Commonwealth Advisory and Technical Service. A sub-committee of the Select Committee regarded this as an indispensable instrument of future assistance to such countries inside and outside the Commonwealth. Besides this, the Committee's examination of financial relations with the dependent territories touches on the mechanism by which grants are made for research and development purposes, and finally the Committee's consideration of proposals for some form of merger of the Colonial Office and of the Commonwealth Relations Office are of wide general interest as well as closely affecting the future of the Overseas Civil Service.

Consideration of the arguments for and against such a merger led the Committee to accept the arguments in favour. The Committee believes that it is desirable from the point of view of efficiency in Whitehall, and that it offers the best way of preserving, for the benefit of independent and dependent territories alike, knowledge and experience that might otherwise be lost. The continued existence of two separate Departments of State to deal with the affairs of a rapidly developing and changing Commonwealth leads to a dichotomy of thought and approach that militates against the unity of the Commonwealth; and the Committee does not regard as well founded the argument that such a merger would not be acceptable to the rest of the Commonwealth. On the contrary, it believes that with the right presentation and given sufficient thought and care, the concurrence of the other independent members of the Commonwealth can be secured, and that the benefits to be gained are so substantial that no effort should be spared to achieve it. In particular, the merger would ease many economic and technical problems during the transition to independence and afterwards.

The Select Committee recommends accordingly that the two Offices should be merged on the lines of a tripartite organization outlined in evidence by Sir Hilton Poynton, the Permanent Under-Secretary of State for the Colonies, in which one of the three sections would be organized functionally with no

distinction between independent and dependent countries, particularly in the field of technical aid, social services and the like. If the full advantages are to be obtained, this step should be taken at once; and the Select Committee recommends further that the new Department should be known as the Commonwealth Office and should be administered by a single Secretary of State, assisted by three or more departmental ministers. These views appear to be shared by Mr. Kenneth Younger, director-general of the Royal Institute of International Affairs, who gave evidence before the Committee, and from time to time such a merger has already been suggested in Parliament.

If such a merger of the two Offices takes place, the establishment of a Commonwealth Advisory and Technical Service will be no less necessary, in the Committee's view, in order to reach the objectives of planning overseas assistance. Moreover, Sir Hilton Poynton also pointed out that economic, educational and research problems do not really differ according to whether a territory is an independent country or whether it is still a dependent territory, and the disadvantages of the present system are likely to become more obvious as less-developed territories such as Tanganyika attain independence. The proposed Service would establish on a rational and more comprehensive basis the present provision for new forms of technical assistance in the shape of the services of experts, and the Select Committee emphasizes that only if aid for new States is granted in an ordered programme can it be properly effective and hence economical to the taxpayers of the United Kingdom.

Establishment of such a Service will enable the maximum benefit to be gained from assistance given to new States during their dependent days, and it would secure for these countries the experience and knowledge of Overseas Civil Service officers who, on retirement from that Service, could continue in the new Service to employ their talents for the benefit of overseas governments rather than take other employment. Finally, this Commonwealth Service should strengthen the links between Commonwealth countries. Recruitment from the Commonwealth, and especially the older countries, and provision by this means of aid by them to young countries, would broaden the basis of the Service and further understanding between Commonwealth countries. These solid advantages are regarded as outweighing the disadvantages of such a scheme, which would not offer a comprehensive solution to the intractable problem of redundancy which already confronts the Overseas Civil Service, though the Committee believes that the difficulty of ensuring graduated promotion for officers in such a Service could be overcome. It emphasizes, however, that it is essential

* Fourth Report from the Select Committee on Estimates, together with part of the Minutes of Evidence taken before Sub-Committee D and an Appendix, Session 1959-60, Colonial Office. Pp. xxxvii+280. (London: H.M. Stationery Office, 1960.) 14s. net.

to safeguard the flexibility and informality of Commonwealth relationships, and it suggests that the administration of the proposed Service in the United Kingdom would require to be entrusted either to a Commonwealth institution, such as the Commonwealth Economic Consultative Council, or to the proposed new Commonwealth Office.

In considering the financial aspects of relations with the dependent territories, the Select Committee directs attention to the urgent need for devising some system to enable Colonial development and welfare programmes to be brought to completion after the expiry of the period for which expenditure was originally authorized. It also comments on Colonial information services and criticizes the refusal of the Colonial Office to accord information officers in the Colonial territories right of direct correspondence on technical matters with the Central Office of Information. Such rights, it recommends, should be granted, especially in territories approaching independence; and it also recommends that, especially in emergent territories, the British Council should seek to enlist local financial support, as such co-operative effort would enhance local appreciation of the services of the Council.

It is against this background, and especially the two major recommendations for the establishment of a Commonwealth Office and a Commonwealth Advisory and Technical Service, that the Committee's discussion of the problems presented by the Colonial Office staff and the Overseas Civil Service is best considered. Despite the present uncertainty of careers in the Colonial Service, the number of candidates expressing a preference for service in the Colonial Office still exceeds the number accepted, partly because of a decline in the standard of candidates. Nevertheless, the Office at present finds it difficult to guarantee careers with proper expectation of promotion, both to its new recruits and to those more senior officers whose careers can only be continued for a full term of years by transfer to other Departments. While there is less reluctance among its staff than three years ago to spend half their time abroad instead of only the two years early in their service to which officers of the Administrative and Executive Class are normally liable, the Select Committee recommends firmly that only staff prepared to serve at home and overseas should be recruited to the Colonial Office in future. Further, to assist in planning the future establishments, the present staff should be asked immediately to state whether they would be prepared to serve abroad, in the event of their being transferred to the Commonwealth Relations Office. The recommendation that Colonial Office staff should spend longer periods on secondment abroad in order to acquire a fuller understanding of the governments and peoples of Colonial territories is clearly intended to apply to the staff of the proposed Commonwealth Office also.

The examination of the Overseas Civil Services emphasizes further some of the points made by Sir Kenneth Younger in his recent book, "The Public Service in the New States", and is based partly on

a memorandum on the Colonial Office and the Overseas Civil Service submitted on behalf of the Colonial Secretary. The numbers of the Overseas Civil Service decreased in 1959 by at least 10,000-14,000, most of whom were employed by the East Africa High Commission and the Governments of Hong Kong, Kenya, Tanganyika and Uganda; but although 1,067 officers were recruited in 1959, at the end of the year there were still 866 vacancies. The main drawback to recruitment is the inability of the Colonial Office to offer a guaranteed career for 25-30 years, owing to the decreasing numbers of posts in territories under the control of the Secretary of State. The suggested Commonwealth Advisory and Technical Service should help to overcome this difficulty, but the Committee is critical of the present conduct of recruitment to the Overseas Civil Service, and it suggests that the Colonial Office should take the initiative among recruiting agencies by revising and modernizing its recruiting methods for such appointments, particularly so as to provide more direct and imaginative forms of contact with university students. It also considers that the Office has not been active enough in seeking recruits from Commonwealth countries, and recommends that the Colonial Office should take immediate steps to promote recruitment from Commonwealth countries to the Overseas Civil Service, both on pensionable and on contract terms. A new approach to the problem of local recruitment is also needed.

The importance of these measures is underlined by events in the Congo and elsewhere during the past year, and it is clear enough that the countries now emerging are likely to have a greater need of the services of overseas officers, because they are less developed than such countries as Ghana and Malaya, the Federation of Nigeria, Cyprus, or the West Indies Federation. Despite the seriousness of the problem of redundancy, which the Committee believes might have been largely solved had the foundation of the Overseas Civil Service in 1954 been more than just a change of name, and would have been alleviated had the Special List A and proposed secondment schemes of 1956 succeeded, it is thought that there is a future for the Overseas Civil Service in a much-reduced form, employed in some territories on terms and in an atmosphere difficult to foresee at this time of rapid change. It is essential, in the view of the Committee, for the United Kingdom to shoulder part of the burden of paying differentials between the salary and allowances of an overseas officer and those of a local officer, and this principle has since been accepted.

Such a measure should help to improve the morale and so to staunch the wastage of overseas officers, while retaining the links between the United Kingdom and the Commonwealth and assisting to ensure the stability and forward the development of emergent countries. Of itself, however, it will scarcely do more than alleviate temporarily the uncertainty clouding the future career of every overseas officer in an emergent country, and the Committee recommends further an urgent and comprehensive examination of the organization and terms of service of the Overseas

Civil Service, taken in conjunction with its recommendation for the establishment of a Commonwealth Advisory and Technical Service.

Though the Select Committee presents the case for a single Commonwealth Office cogently and persuasively, if not altogether conclusively, taken by itself it is unlikely to meet the most urgent needs. Far more important than the elimination of overlapping and the financial savings which a new administrative arrangement might permit is the question of outlook and the whole tempo of administration. This is indeed recognized by the Committee, which noted, moreover, that some increase in staff in consequence of the greater need for technical services in the dependent territories might be unavoidable, and again that there was likely to be increasing need for officers with technical rather than purely administrative qualifications. The evidence submitted points clearly to the danger that, without some merger, the existing Colonial Office advisory staff of 58 dealing with such questions as agriculture, animal health, education, fisheries, flora and fauna, medical research, etc., may be dispersed, and also that the important research programmes now maintained from Colonial Development and Welfare Funds may be interrupted when territories come to independence.

The essential recommendations of the Committee are those relating to the Overseas Civil Service and to the establishment of a Commonwealth Advisory and Technical Service, and they have the prior claim on the Government's attention. They are more important than financing the projected scheme of technical aid to which Mr. Iain Macleod referred on October 12 during the Conservative Party meeting at Scarborough, and which is unlikely to be effective unless prior attention is given to the means by which such aid is to be channelled and the conditions of service to be offered to those who are expected to provide such assistance. Unless those conditions are reasonable and appropriate, it may prove impossible to recruit staff of the high quality required, still less to expect from them the standards in which enthusiasm and efficiency are fostered. Like Mr. Kenneth Younger in "The Public Service in New States", the Select Committee puts the emphasis in the right place—on the human factor, on the men and women who will provide the required services, and on the conditions under which they will be expected to work. With this report before it, the Government cannot just leave the problem to such bodies as the newly formed Overseas Development Institute; and in view of the demand that technical assistance makes on the services of scientists and technologists of all kinds, it is to be hoped that the Overseas Research Council, with the full support of the Minister for Science and the Advisory Council for Scientific Policy, will lend the full weight of its influence in the establishment of satisfactory conditions for overseas service, and the urgent and thorough examination of the desirability of establishing a Commonwealth Advisory and Technical Service as the Select Committee recommends.

A CENTURY OF PROGRESS IN EVOLUTIONARY BIOLOGY

Darwin's Biological Work

Some Aspects Reconsidered. By P. R. Bell, J. Challoner, J. B. S. Haldane, P. Marler, H. L. K. Whitehouse and J. S. Wilkie. Edited by P. R. Bell. Pp. xiii+343+5 plates. (Cambridge: At the University Press, 1959.) 40s. net.

THIS valuable book consists of six excellent chapters on the present position of a number of the biological topics on which Darwin himself worked. Unfortunately the inept title, which suggests a work of purely historical interest, is likely greatly to hinder sales. This is a pity because it deserves to be in every scientific library and widely read among senior students.

The opening chapter by P. R. Bell, who edits the volume, summarizes a century of research on the movement of plants in response to light. Among the many important conclusions emphasized is the fact that the study of phototropism has become intimately connected with the basic problems of cell physiology—a conclusion which would certainly have astonished Darwin, who at least in his theorizing on natural selection was inclined to regard the animal or plant as 'given', and who was not much attracted to physiology. Bell points out that among the implications of modern views as to phototropism is the conclusion that the current division of botany into two more or less independent disciplines—morphology and physiology—is neither sound nor likely to be profitable. The other botanical chapter also takes the form of a most able review, by H. L. K. Whitehouse, of a hundred years progress in the study of cross- and self-fertilization of plants. One of the most topical subjects which emerges from this discussion is that of cytoplasmic inheritance and the respective parts played by nucleus and cytoplasm in hereditary transmission.

Perhaps the two zoological chapters constitute the most outstanding feature of the book. The first is by J. B. S. Haldane and is entitled "Natural Selection". In a little less than fifty pages Haldane contributes a review of the subject which is masterly in its simplicity and lucidity and yet at the same time profound. It is hard to imagine how it could have been better done. However, the last two-and-a-half pages, which deal with philosophical difficulties and implications of Darwinian theory, are open to some criticism. Here the writing is too condensed, and statements are made without sufficient explanation and support; although it is probable that if he had given himself more space the writer might well have been able to provide these. Thus he states that the difficulty in assuming mind to be a product of evolution does not arise for a consistent idealist, nor for a consistent materialist. Whatever may be the idealist position, this is certainly not true for what is normally understood by the term 'materialist'. Although Haldane has a few words to say as to what he himself means by this term in relation to some Chinese and Hindu philosophical concepts, he does not say enough to make the matter clear. Another idea which it would have been good to have further developed arises from the suggestion that Darwin may have started a revolution in philosophy as great as that initiated by Aristotle, whose logic is mainly based on his efforts to classify animals. Darwin, in comparing species,

pointed out that in studying any two forms we shall be led to weigh more carefully and to value higher the actual amount of difference between them. Haldane suggests that some future philosophy will be based on differences whereas to-day's common-sense philosophy, Aristotelian in origin, is based on similarities. He considers that this may in due course have a profound effect on the outlook both of scientists and philosophers on the natural world.

Among all Darwin's writing "The Expression of the Emotions in Man and Animal" (1872) was perhaps exceeded in originality only by "The Origin" and "The Descent of Man". Its impact was long delayed, but none the less great when it came. P. Marler provides an admirable chapter on subsequent developments in the study of animal communication. He deals with chemical, visual and auditory communication in both invertebrates and vertebrates, and summarizes for the first time in this connexion a great deal of the modern ethological literature. His chapter is profusely illustrated, and the sections on the evolution of bird song, on the origins of communication and on animal and human language are of particular interest. The book is completed by a valuable account of palaeontology and evolution by J. Challoner, who pays particular attention to the imperfections of the geological record, the question of group evolution and evolutionary series.

Finally, a chapter by J. S. Wilkie on the originality of Darwin's theory of evolution shows him to be an expert on the work of Buffon and Lamarck, and consequently he is able—in contrast to many modern writers on this subject who take their views second-hand—to give an authoritative assessment of the scattered suggestions as to the possibility of evolution in the works of the former. In regard to Lamarck, he points out that it was his deistic assumptions which gave his theory its peculiar structure. Lamarck supposed that God, in directing the process of evolution, was aiming directly at the production of man and that for this reason linearity should be empirically discoverable in the evolutionary series. It is characteristic of deism to assert that the mind of God is infinite yet to suppose that we can see things from God's point of view. Believing this, Lamarck was unable to tolerate the idea that any species should be 'wasted' on the way towards the production of man so he is unwilling to admit the possibility of extinction. It was these presuppositions and their consequences which made the Lamarckian theory unable to adapt itself readily to the data of comparative anatomy, and even less able to assimilate the fossil record, which of course shows no simple upward trend of organization. Wilkie's chapter brings to a conclusion a valuable and distinguished book.

W. H. THORPE

RADAR IN WEATHER RESEARCH

Radar Meteorology

By Louis J. Battan. Pp. xi + 161. (Chicago: University of Chicago Press; London: Cambridge University Press, 1959.) 45s. net.

WHEN it was discovered that centimetric radar could detect precipitation, the meteorologist found himself in the possession of an almost embarrassingly powerful tool for weather research. Since

the end of the War, meteorologists in many countries have used the spare military radars which became available to make great advances in precipitation physics. There is a use, too, for radar in weather forecasting, and now that State meteorological services are acquiring their own weather-radar sets, increasing numbers of meteorologists are being introduced to this technique.

There have been few general surveys of progress in this field, or accounts of radar theory from a meteorological aspect, and the newcomer to the subject has been faced with the task of acquiring the basic physical principles from text-books, of finding out the workings of his radar equipment from the technicians and of abstracting past research work from a mass of published papers. This slim volume by one of the foremost radar meteorologists in the United States is written for these, and for others with a more superficial interest in radar meteorology. Although more than one-third of the book is devoted to radar theory, they will learn little physics and less electronics from it. After an all too brief chapter on the fundamentals of radar and the types of indicator units normally encountered, and a sketchy introduction to the theory of propagation of electromagnetic waves, the standard equations for the detection of spherical and non-spherical water and ice particles are produced. While the Rayleigh approximation can be used at centimetric wave-lengths for rain, hailstones exist in sizes well outside the Rayleigh region. It is surprising therefore that no reference is made to Ryde's wartime work showing the very high back-scattering cross-sections of larger ice spheres (recently confirmed by the author's own calculations).

The difficulties encountered in the quantitative use of radar are perhaps too well brought out in the chapter on precipitation measurements. The power received back by the radar is proportional to the sum of the sixth powers of the drop diameters. In order to deduce rates of rainfall or other meteorological data, it is necessary to make assumptions about the drop-size distribution law, and it is encouraging that reasonable results can be obtained when this is done. No attempt is made to explain the large discrepancy between observed and calculated values of echo power which has been found by all those attempting to obtain quantitative values from signal intensity measurements.

The greater and more useful part of the book is devoted to a discussion of the use made by meteorologists of centimetric, and more recently of millimetric, radars. Here the author, being a meteorologist, is on happier ground, and has produced a valuable and concise account of research in this field during the past 10–15 years. Inevitably there is emphasis on American investigations into severe weather, both from thunderstorms and hurricanes, which in themselves are of little interest to some readers. Nevertheless every country has its own weather problems, and their analysis by radar techniques will lead, as this book indicates, to a better understanding of cloud and precipitation physics.

There are two notable omissions in the list of chapter headings on the uses of radar. No specific mention is made of the value of radar to the synoptic meteorologist. While it may be true that the forecaster has no use for radar information, an appraisal of the value of the data for forecasting research would have been of great interest. Neither is there mention of the allied problem of the analysis and dissemination of radar data, a problem which will increase in magni-

tude as radar sets are made to produce more and more data required for use operationally.

A chapter on 'angels' shows that argument is still strong on the causes of echoes received from apparently clear air. The book concludes with a chapter on special instrumental techniques, which might well have come at the end of the theoretical section, since some of the techniques are referred to thereafter. There is no doubt that the meteorologist is now developing radar sets to meet his special needs, and we can expect progress to become even more rapid than over the initial fifteen years of radar meteorology covered by this book.

The book is well produced and there are adequate references, although the method of giving references as footnotes, liberally sprinkled with *op. cit.* and *ibid.*, is at times irritating. The small circle of prospective buyers presumably necessitates the high price.

J. R. PROBERT-JONES

DELINQUENT BOYS AND THEIR PARENTS

On the Threshold of Delinquency

By John Barron Mays. (Social Research Series.) Pp. x+243. (Liverpool: Liverpool University Press, 1959.) 25s. net.

Delinquency and Parental Pathology

A Study in Forensic and Clinical Psychology. By Dr. Robert G. Andry. Pp. xv+173. (London: Methuen and Co., Ltd., 1960.) 21s. net.

EACH of these books is a study of a small group of delinquent boys—but they have little else in common. Mr. Mays has written an engaging account of an attempt to deal with a particularly difficult bunch of youngsters by setting up a youth club in a delinquent area. No systematic description is given of what actually went on inside the Dolphin Club and one has only a vague picture, for example, of the number of staff engaged, of the use and misuse of equipment, and what a normal week's programme looked like. But a much more important point is made and illustrated with a wealth of detail, that the Club succeeded in keeping boys off the streets and enlisted the co-operation of otherwise indifferent parents in achieving this and possibly other aims.

There are three main strands running through the work: (a) an account of incidents and activities in and around the club; (b) pen pictures and case-histories of the club members; (c) many observations on the social patterns of the district and on the nature of delinquency in general.

The book is somewhat discursive, and the author moves rather too freely from one topic to another. But the observation is shrewd, the descriptions are vivid, and the commentary is uncommonly penetrating. The reader's interest is held, and at the end one has a clear picture of a courageous experiment carried out by people who had no illusions but who were not thereby discouraged. Their achievement is clear and the book is both informative and encouraging.

In a particularly discerning passage (pp. 26–28), Mr. Mays gives an overall estimate of the major factors underlying delinquent behaviour in adoles-

cents. He brings out clearly the difficulties of "boys approaching adolescence who require a strong father figure with whom they can identify themselves". This is, to a large extent, the text of Dr. Andry's remarkable study. Here eighty delinquent boys in a remand home are compared with eighty non-delinquent boys from a reasonably matched group. Following a systematic interview of each of these boys and of thirty sets of parents in each group, he examines parental roles as perceived by the boys and also the parents' perception of their own roles. He concludes that delinquent boys "tend to perceive greater defects in their fathers' roles than in their mothers' roles, whereas non-delinquents tend to perceive the roles of both parents as being adequate. (Further, this seems confirmed in the main by both parents)". This general conclusion is followed up by detailed investigation on specific points, and the differential response of the delinquent and non-delinquent is subjected throughout to a statistical test of significance. For the most part the differences between the responses of the delinquent and the non-delinquent group are most impressive.

In his introduction to Dr. Andry's book, Dr. Mannheim implies that some special interest in fathers is a not unexpected reaction to Bowlby's now classic theory of the effects of early maternal deprivation. This may be so, but Dr. Andry's study and Dr. Bowlby's work are not strictly comparable. Andry specifically excludes neurotic cases (though he does not define the term) and his technique is confined to questioning adolescent boys (between the ages of 11 and 15 years) and some of their parents. Since he excludes (for perfectly good reasons) children with an I.Q. below 80 and also children from broken homes, his sample is by no means representative of the delinquent population. He might, quite probably, obtain similar results from a wider sample. Bowlby claims to have shown a clear connexion between early traumatic maternal deprivation and subsequent maladjustment (not necessarily delinquent). Moreover, a high proportion of the cases in which he is interested could properly be called neurotic or psychopathic. This is not inconsistent with, but is quite different from, assessing the respective roles of father and mother during the adolescent period.

Dr. Andry's book is somewhat repetitive and his language is occasionally obscure (for example, "a research worker may use a set of data to derive a maximal system of control with respect to the end object via the possible decision"). But the experiment which he describes is rigorously planned and his use of statistical methods is judicious. A short review of the literature and an extremely interesting bibliography are included. This is a study which will certainly have a considerable effect on future thinking and its direct implications so far as case work is concerned are obvious.

One striking fact is mentioned by both Mays and Andry. The delinquent boy is often keenly aware of his father's defects, and particularly of the poor relationship between boy and father. Father and mother are equally aware of the situation; and all the parties concerned would like to see it improved (though their thoughts and feelings may be vague and confused). Experience strongly confirms this, and it seems that actual teaching of the basic techniques of father-son relationships—and particularly the overcoming of embarrassment on both sides—is often surprisingly effective.

JOHN GITTINS

THE NEW RADIO ASTRONOMY CENTRE OF THE UNIVERSITY OF SYDNEY

By PROF. H. MESSEL

THE Chatterton Astronomy Department of the School of Physics, and the School of Electrical Engineering, have established a Radio Astronomy Centre in the University of Sydney.

Radio astronomy is concerned with observations of the heavens at radio wave-lengths rather than with light waves. It is a relatively new and vigorously growing branch of one of the oldest of the sciences, and Australia has taken a leading part in its development. Almost all the Australian work, so far, has been carried out by the radio astronomy group in the Radiophysics Division of the Commonwealth Scientific and Industrial Research Organization.

mers, including Dr. B. Y. Mills, to the Chatterton Astronomy Department and the recent appointment of Prof. W. N. Christiansen, formerly of the Commonwealth Scientific and Industrial Research Organization radio astronomy group, to the chair of electrical engineering at the University of Sydney, has made possible the establishment of the new Radio Astronomy Centre. The Centre will mean the pooling of resources, intellectual and material, of the Schools of Physics and Electrical Engineering for an attack on some of the major fundamental problems of radio astronomy. The basic interest in the School of Electrical Engineering in solid-state devices and low-

Fig. 1. Artist's sketch of the giant Mills' cross for the University of Sydney Radio Astronomy Centre

Recently, however, several members of this group have joined the staff of the University of Sydney, and, in addition, several outstanding English radio astronomers have already joined, or will soon join, them. Most of these are in the Chatterton Astronomy Department of the School of Physics under Prof. Harry Messel. One group, led by Dr. B. Y. Mills, who was previously with the Commonwealth Scientific and Industrial Research Organization, will engage immediately in radio astronomy work. Another, in which Dr. R. Q. Twiss of the School of Physics and Prof. Hanbury Brown of the University of Manchester will join forces, will work with the giant stellar interferometer in the optical field of astronomy.

Radio astronomy, however, is the meeting point of astronomy, physics and all the most advanced techniques of electronics and electrical engineering. The appointment of a group of leading radio astrono-

noise receivers will contribute a great deal to this joint action.

One of the first problems to be considered by the Radio Astronomy Centre is that on which Dr. Mills has been engaged for some years: the detailed observations of sources of radio emission, both in our own Galaxy and in the very distant regions of space. Such observations are very important for a study of the physics of the rare gaseous medium, lying around and between the stars, which probably holds the key to the problem of the formation and evolution of galaxies such as our own, the Milky Way system. These observations are of particular importance to the School of Physics, which is already established as a leading centre of cosmic-ray research, because it has been shown that there is a very close connexion between cosmic rays and the cosmic radio emissions observed at wave-lengths of 1 m. or longer. It is hoped also that a study of the weakest radio-sources

will yield valuable information about the distribution and state of matter in the most distant regions of the universe and perhaps help to answer the age-old question as to its origin.

For the new studies a very large radio telescope will be needed, far too large to be built in a completely steerable form, such as the large paraboloid being constructed by the Commonwealth Scientific and Industrial Research Organization at Parkes. The radio telescope needed for this work must have dimensions of about one mile, and the most suitable form for this is a cross-like structure invented by Dr. Mills and called a Mills cross. The cost of a radio telescope of this type and size will be about £300,000.

The Chatterton Astronomy Department, supported by the Nuclear Research Foundation, has set aside £100,000 for the first stage of this telescope. The rest of the cost to complete the instrument to its full size must be raised elsewhere by the Schools of Physics and Electrical Engineering of the University. During the next year, when the first stage of the telescope is being designed and construction commenced by Dr. Mills and his collaborators, Prof. Christiansen will be in Holland engaged in a design study for a similar instrument for a Benelux research foundation. Because of the different conditions it is probable that the details of the two instruments will be very different. This close international collaboration is typical of many astronomical projects and should be of great benefit to astronomy in both countries.

Although the design of the Sydney radio telescope has not been completed, the broad specifications are already decided (Fig. 1). It is intended to operate at two different wave-lengths, near 75 cm. and near 3 m. The shorter wave-length is the basic one, and will give the higher sensitivity and resolution; the beam-width will be less than 3 min. of arc with the planned size of 1 mile. The longer wave-length will

be used to obtain spectral information, particularly of optical emission nebulae for which observations in the neighbourhood of this wave-length are most important.

The arms of the cross will be in the form of cylindrical parabolas with 'line' feeds for the two wave-lengths at their foci. It will be possible to direct the instrument in the meridian plane, partly by mechanical and partly by electrical means, rotation of the Earth bringing all parts of the sky, within the coverage of the instrument, into view. Emphasis is being placed on rapid alteration of the setting of the radio telescope so that many selected objects can be studied in a single night's observation; at the same time a number of simultaneous records at closely spaced elevations produces the analogue of a photograph taken with an optical telescope. Because of the vast amount of data which will be produced by the instrument, the principal output will be in digital form on paper tape, and for analysis will be fed directly into *Silliac*, the electronic computer of the School of Physics.

This instrument will combine very well with the 210-ft. steerable radio telescope of the Division of Radiophysics, which is designed primarily for operation at shorter wave-lengths, down to 10 cm., including the *H*-line wave-length of 21 cm. The conjunction of these two very powerful instruments in studies of the southern skies, particularly of the central regions of the Milky Way and the closest of the external galaxies, the Clouds of Magellan, is an exciting prospect for Australian radio astronomers.

The joint effort of the Schools of Physics and Electrical Engineering in this ambitious undertaking is without parallel in the University of Sydney, or indeed in any Australian university, and may help substantially in setting a pattern for the more effective introduction of advanced research into the universities of Australia.

THE INTERNATIONAL GEOPHYSICAL YEAR

A SYMPOSIUM on the "International Geophysical Year", arranged by Section A (Mathematics and Physics) of the British Association, was held in Cardiff on September 1.

Dr. R. Stoneley opened the symposium with a reminder that the idea of international co-operation in scientific matters is by no means a modern one. Sir Graham Sutton has pointed out that in 1861 the American meteorologist Commander F. M. Maury, in an article in the *British Association Notices and Abstracts*, strongly advocated international co-operation in the scientific exploration of the Antarctic. However, the suggestion was not followed up, and it was not until 1882-83 that the First International Polar Year marked the commencement of scientific collaboration in polar research: observations were made in arctic regions of aurora, geomagnetic and meteorological phenomena. Fifty years later, 1932-33, the Second International Polar Year included as new features the observation of weather conditions above ground-level by means of radio-balloons, and the investigation of the ionosphere by radio.

It was too much to expect scientists to wait until 1982 for another Polar Year, and in 1950, Louis V. Berkner and Sydney Chapman suggested to the

Mixed Commission on the Ionosphere that the Third International Polar Year be held only 25 years after the second, with the advantage that 1957-58 would coincide with the expected sunspot maximum. This project was recommended by that Commission to the three parent Unions (Union Géodésique et Géophysique Internationale, International Astronomical Union, Union Radio Scientifique Internationale) and was approved in 1951 by the International Council of Scientific Unions, which appointed a special committee, to be known later as the Comité Spécial de l'Année Géophysique Internationale, with Prof. S. Chapman as president; the name of the project was changed to 'International Geophysical Year', embracing the whole Earth, and not merely the polar regions. The duration of the International Geophysical Year was extended to the eighteen months July 1, 1957-December 31, 1958. By the commencement of the Year the number of nations participating had grown to 67.

The scientific activity was divided among 14 'disciplines': (1) World Days and Communications; (2) Meteorology; (3) Geomagnetism; (4) Aurora and Airglow; (5) Ionosphere; (6) Solar Activity; (7) Cosmic Rays; (8) Longitudes and Latitudes;

(9) Glaciology; (10) Oceanography; (11) Rockets and Satellites; (12) Seismology; (13) Gravity Measurements; (14) Nuclear Radiation. Each of these was represented on the Comité Spécial de l'Année Géophysique Internationale by a reporter. Correspondingly, national committees were set up in the participating countries, with reporters for each discipline. In all, five conferences of the Comité were held, in addition to conferences of special groups. The general plan was that all observational data were to be collected and sent as promptly as possible to the three appropriate World Data Centres, of which the first was in Washington, D.C., the second in Moscow, and the third in centres different for various disciplines. Thus, there should be in existence a triplicate centralized record of the observations relating to each discipline: notification of each despatch of data to the Centres was sent to the co-ordinator of the International Geophysical Year (Vice-Admiral Sir Archibald Day) at Brussels. To co-ordinate more efficiently the taking of observations a calendar of World-Days was drawn up, indicating the days on which there should be a special concentration of observational work. In addition, provision was made for a world-wide distribution of warnings of special events, such as outbreaks of solar activity.

All this central organization, however economically managed, involved considerable expenditure. The earlier expenses were borne by the International Council of Scientific Unions, which by the end of the International Geophysical Year contributed some £14,000 to the project. More than double this amount, about £30,000, was paid by Unesco during the same period, during which the participating nations themselves contributed some £60,000. But this total sum of about £100,000 is small compared with the total expenditure, principally by the participants, of a sum of the estimated order of £300,000,000—a tribute indeed to the efficiency of the central organization.

The task of publishing the results of the International Geophysical Year is an onerous one. A scheme of publication of the *Annals of the International Geophysical Year* was approved by the Comité Spécial de l'Année Géophysique Internationale with the help of an advisory committee presided over by Gen. Laclavère and later by Dr. D. C. Martin, with Sir Harold Spencer Jones as general editor until May 1958, when this task was transferred to the secretariat of the International Geophysical Year. To secure co-ordination of observational work, a series of four "Instruction Manuals" was published well ahead of the Year. The complete series of the *Annals* will deal with the history and planning, as well as national programmes, lists of International Geophysical Year stations, summaries of results with their analysis, interpretation and discussion, bibliographies and catalogues of material available at World Data Centres. Evidently some procedures, such as access to data at these Centres, will need to be developed or modified according to needs and experience. Analogous problems, such as publication and storage of data, will fall to the lot of individual countries. In Great Britain, for example, the Royal Society has well in hand the publication of the Halley Bay Observations, under the editorship of Dr. D. C. Martin.

Something should be said about the continuation of the International Geophysical Year effort after the end of 1958. The manifest success of the plan

led to the proposal at the fifth conference of the Comité Spécial de l'Année Géophysique Internationale at Moscow in the late summer of 1958 that the International Geophysical Year period should be extended to the end of 1959, making 2½ years in all. Not all the nations involved could assent to this scheme, since in some cases the national commitment was explicitly limited to the original 18 months. It was, however, unanimously agreed that, so far as practicable, observations should be continued throughout 1959 under the title of "International Geophysical Co-operation", with the central organization bridging the gap until a smaller special committee could take over the functions of the Comité Spécial de l'Année Géophysique Internationale. Some of the International Geophysical Year disciplines that are otherwise catered for have been dropped, and two new disciplines, aeronomy and palaeogeophysics, have been included*.

The Antarctic claimed special attention. As H. Wexler pointed out, essentially for seven reasons: (1) It is a large part of our planet; (2) it contains 86 per cent of the world's glacial ice; (3) it is the most efficient cold air factory, and contains the South Pole; (4) the melting ice generates the antarctic bottom current; (5) it is the region of the aurora australis; (6) it contains the south magnetic pole; (7) it presents a stable platform for the investigation of the thermal and electrical properties of an atmosphere cut off from sunlight for many months of the year. Thus, it is not surprising that 12 nations sent expeditions to Antarctica.

During 1954 the Vahsel Bay region of the Weddell Sea was recommended by the Comité Spécial de l'Année Géophysique Internationale at a conference in Rome as a suitable place for a station on the Antarctic continent, and the Royal Society decided to send an expedition there. An advance party late in 1955 erected the base hut at Halley Bay; the main party arrived on January 4, 1957. The leader of the expedition was Col. R. A. Smart, who later was succeeded by Mr. J. MacDowall.

Taking part in the symposium held by the British Association were: Prof. W. J. G. Beynon, who was reporter for the ionosphere, both on the Comité Spécial de l'Année Géophysique Internationale and on the U.K. National Committee for the International Geophysical Year; Mr. J. MacDowall, who, as mentioned, had for part of the time the leadership of the Halley Bay Expedition, in addition to his heavy responsibilities for observations in meteorology, glaciology, seismology and geomagnetism; Dr. G. E. R. Deacon, chairman of the U.K. National Committee for Geodesy and Geophysics, and national correspondent for oceanography.

Ionospheric Observations

Ionospheric studies formed a major part of the overall programme of the International Geophysical Year, and some of the early results of these studies were described by Prof. W. J. G. Beynon of the University College of Wales, Aberystwyth. The most important type of study—vertical radio soundings—was carried out at more than 160 stations. Work on radio-wave absorption by the ionosphere was carried out at some 40 stations by the conventional ground-based method and at a further 30 stations by a method

* The writer wishes to express his indebtedness to Prof. S. Chapman's article, "The International Geophysical Year", published in Vol. 1 of the I.O.S.U. Review, January 1959.

which employs radiation from radio stars. Movements in the ionosphere formed a special investigation at a further 36 stations. This radio work on the ionosphere was supplemented by other investigations, including rocket and satellite experiments.

In siting the ground-based stations, high priority was given to the equatorial zone since earlier work had indicated that the ionosphere exhibits a number of anomalies in the locality of the magnetic equator. These investigations have confirmed that in the uppermost layer of the ionosphere (the F_2 layer) there is a belt of low electron density centred on the magnetic equator, with maxima located some 15° – 20° of latitude away on each side. At times the densities at these maxima are as much as three or four times that in the equatorial trough. Theoretical work suggests that these maxima north and south of the magnetic equator result from a movement of high-level equatorial ionization outwards along the magnetic field, and the results now available from the close network of ionospheric stations tend to confirm this suggestion.

A second equatorial problem, for which the results obtained during the International Geophysical Year have already been published, concerns the 'equatorial electro-jet'—an intense but narrow current system, postulated by magneticians to account for abnormally large magnetic variations observed at equatorial magnetic observatories and notably at Huancayo. A series of rockets launched during the International Geophysical Year by U.S. workers from a ship-borne launcher, at latitudes between 4° N. and $2\frac{1}{2}^\circ$ S., show that the equatorial electro-jet is limited to a zone of only about 3–4 degrees of latitude around the magnetic equator, and that it flows in one or more current sheets of thickness about 10 km. at levels of 95–125 km. above the ground.

It has long been appreciated that disturbances in the Earth's magnetic field, and associated disturbances in high latitudes in the form of auroræ, are very probably caused by electrically charged particles entering the Earth's atmosphere from outside and being guided towards high latitudes by the terrestrial magnetic field. More than 50 years ago the Norwegian physicist Störmer made an extensive analysis of the trajectories of solar electrically charged particles as they approach the Earth, and published theoretical curves of particle precipitation in high latitudes. Investigations during the International Geophysical Year, by British workers, of two distinctive polar ionospheric phenomena (the 'radio black-out' and polar sporadic-E ionization) have shown that the incidence of these two phenomena and their variations with latitude are of the general form predicted by Störmer's 'precipitation curves'.

The incidence of streams of charged particles at high latitudes might be expected to give rise to an increase in the temperature of the upper atmosphere. Strong evidence that this is in fact the case has come from rocket soundings at Fort Churchill (latitude 59° N.) and at White Sands (latitude 33° N.). Above about 200 km. the average temperature at Churchill is some 1,200 degrees higher than at the lower-latitude station.

Geomagnetic and Seismic Observations

Mr. J. MacDowall gave an account of the Royal Society's expedition to Halley Bay. A suitable site $1\frac{1}{2}$ miles from the sea on a floating ice-shelf had been

found by a ten-man advance party in January 1956, and a living hut 130-ft. long was erected. This was then the largest building in Antarctica, a record which will now undoubtedly be claimed elsewhere. With this advance party in the field during 1956 the main party in Great Britain were able to plan their preparations with a good appreciation of some of the practical problems facing the establishment of the scientific programme. One of the most serious problems was the mutual electrical interference; fortunately this did not greatly affect the carrying out of seismic and geomagnetic observations. The main problem was perhaps the situation of the observatory on what is now called the Brunt Ice-Shelf, which was about 50 km. long and 140 m. thick, floating in about 190 m. of sea water; the relative dimensions can be represented by a board of wood $\frac{1}{4}$ in. thick and 10 ft. long overlying $\frac{1}{4}$ in. of water.

Such a situation was not considered ideal for seismic and geomagnetic recorders, which are ordinarily built on a firm subsoil-rock if possible. The advance party, the Building Research Station and the Scott Polar Research Institute contributed to the eventual solution of the problem of the geomagnetic instrument foundations, which were formed by driving 13 wooden telegraph-poles 20 ft. into the compacted snow of the ice-shelf; these reduced differential movement and formed a satisfactory vibration-free foundation. Snow accumulated on the flat upper surface of the ice-shelf at the average rate of 3 ft. per year (density 0.36 gm. cm. $^{-3}$); it afterwards became compacted and spread out, with the result that the ice-front, or coast-line, moved outwards, taking the Base with it at about 400 m./year. At the same time the Base rotated by about 0.5° a year, so that regular astronomical observations were needed in order to find the true orientation of the recording magnets.

The seismic recorders were tried in several situations, and were eventually installed at the bottom of a 30-ft. pit, the floor of which was sufficiently firm, and free from local vibration due to the nearby Base: at that depth the compacted snow has the consistency of soft sandstone. In this site the arrivals of longitudinal waves originating in any part of the world were well recorded; secondary phases and shear waves, however, were not well recorded, even from nearby earthquakes in the South Shetland Islands about 1,200 km. away. In seismological work, the first arrivals are undoubtedly the most important and to this extent the seismological readings were quite satisfactory.

On the question of the continuation of observations at Halley Bay, Mr. MacDowall considered that on the observational side the issue is clear out, as much is now known that was unknown in 1956. In view of the unique situation of the Base it would be highly desirable to bring the Base up to the ideal geomagnetic observatory standard by making quick-run recordings and measurements of space gradients; tests should be made of other and better types of seismic instruments.

Oceanography

Dr. G. E. R. Deacon remarked that the main idea of the International Geophysical Year was to co-operate in work that needs world-wide networks of observations. Oceanographers exploited the idea by studying changes in mean sea-level, long waves

propagated across the oceans, and the general circulation of the oceans.

Mean sea-level, he said, is not the unalterable datum often implied in everyday usage; at the very first meeting of the British Association, indeed, Sir John Lubbock emphasized the importance of studying the effect of barometric changes on the height of the tide. Sir James Clark Ross in the 1840's found that the ocean behaved like a vast water-barometer; variations of temperature and density of course have to be taken into account.

From data compiled by the International Association of Physical Oceanography it was shown by Patullo, Munk, Revelle and Strong that the sea-level is usually lower in spring than in autumn, the range varying from a few cm. at island stations in low latitudes to 165 cm. in the Bay of Bengal. Near the British Isles the mean sea-level is 15-20 cm. higher in autumn than in spring; most of this can be accounted for by differences of temperature and pressure, but part may be due to the storage of water on the land during the winter months. Some of the fluctuations from year to year are attributable to changes in climate, but the actual rise and fall of the land seems to play a part in it. Variations of mean sea-level become of practical importance in coastal defence against inundation.

Another matter of practical importance arises when a seismic surge or tsunami (popularly called a 'tidal wave') travels across an ocean from the seat of a submarine earthquake in the form of waves which cause considerable damage and loss of life when they impinge on the sea shore. Since the wavelength is in practice many times the depth of the ocean, the waves travel with speeds $(gh)^{1/2}$, corresponding to the usual theory of long waves in shallow water, where g is the acceleration due to gravity and h is the depth of the water. Thus, the ordinary speed of travel is 400-550 miles per hour. On April 1, 1946, for example, a submarine earthquake near the Aleutian Is. gave rise to waves which reached Hawaii 4½ hr. later, causing great loss of life and much damage. At Valparaiso these waves were still 5 ft. high, and in the Antarctic were large enough to wash away an old hut left by the British Graham Land Expedition. Since that disaster a warning system, based on the recordings of earthquakes, has been instituted in the Pacific; during the International Geophysical Year long-wave recorders were installed on many oceanic islands as well as on continental margins, and their records have added much to the knowledge and development of the subject.

After 150 years of ocean exploration there are sufficient observations of temperature and salinity at all depths to give a general idea of the large-scale movements of oceanic waters. Dr. Deacon gave as an example the deep current starting between Greenland and Labrador, where cold water with a fairly high content of salt sinks and spreads southwards at depths of 2,000-3,000 metres. The flow is continued, with a reinforcement of water of high salinity from the Mediterranean, as far south as 50° S., where it rises and forms a stratum between a large wedge of Antarctic bottom water and a shallow layer of Antarctic surface water. This current has been traced round the Cape of Good Hope into the Indian Ocean and south of Australia into the Pacific Ocean. These bodies of water, though moving slowly, transport large quantities of heat and considerably affect the mechanics and productivity of the oceans. During

the International Geophysical Year a notable advance was made in the direct determination of the velocity of flow by using a simple form of float devised by Dr. J. C. Swallow. This could be arranged to float at a predetermined depth and give out sound signals by means of a simple circuit and a magnetostriction oscillator. The results have been surprising: for example, a southward counter-current below the Gulf Stream was observed to flow at 1/3 knot, water at a depth of 2½ miles north-east of Bermuda moved northward for several days at nearly 1 knot, while U.S. scientists have found an equatorial subsurface current in the Pacific flowing at 2½ knots.

In all, Dr. Deacon considered the oceanographic work carried out during the International Geophysical Year to be an undoubted success. It brought to light more problems than it solved, and has led to other co-operative schemes.

Conclusions

Summing up the symposium, Dr. Stoneley remarked that while some of the discoveries have been spectacular, such as the van Allen belts, only the lapse of time will permit an adequate appraisal of all the results of the International Geophysical Year. The geophysical conclusions will gradually fall into their place in this rapidly developing science, but, as with the explosion of Krakatoa in 1883, some of the observations will undoubtedly be of value in lines of research as yet quite unforeseen. Many of the benefits are already clear, even if it is premature to assess their relative importance. However, Dr. Stoneley mentioned in particular the following:

(a) Support has been forthcoming for large-scale and expensive projects which, without the stimulus of the International Geophysical Year, would not have been undertaken. This is particularly true of Antarctic expeditions.

(b) There has been a great stimulus to research in geophysics. In seismology, for example, it has resulted in the setting-up of a number of new stations, of re-equipping and modernizing some of the older ones, and in planning new large-scale lines of research. Likewise, a new magnetic survey of the Earth has been planned.

(c) The general public has become much more aware of the background and the development of geophysics. Radio and television broadcasts have been extremely effective.

(d) The interrelationship of different disciplines has been emphasized. For example, the determination of the inertial constants of the Earth from observations of artificial satellites, linking up with the gravitational field of the Earth and its internal constitution; the world-wide programme of micro-seismic observations, linking oceanography, meteorology and seismology.

(e) The closer association of scientists, whether of the same or of different nationalities, by correspondence, interchange of publications and personal discussion.

Finally, Dr. Stoneley raised the question of the next International Geophysical Year. His own view was that the rapid advances in geophysics would call for another such project sooner than 1985. However, such occasions of international co-operation while stimulating are expensive. It is also conceivable that an overdose of stimulants may not be in the best interests of geophysics.

R. STONELEY

EFFECT OF NOISE AND VIBRATION ON MAN

THE prefix, bio-, attached to the names of various disciplines among the physical sciences, is becoming increasingly familiar to workers outside the biological field as the specialties in applied biology increase and multiply. One of the sessions in Section G (Engineering) of the recent British Association Cardiff meeting was entitled "Bio-mechanics" and was devoted to two topics in the field of what the Americans are now calling 'bio-acoustics'. Prof. E. J. Richards, of the Department of Aeronautics and Astronautics, University of Southampton, spoke on "Noise Annoyance and its Assessment", and Flight-Lieut. J. C. Guignard, Royal Air Force Institute of Aviation Medicine, delivered a paper on "Some Effects of Low-Frequency Vibration on Man" under the co-authorship of himself and Mr. A. Irving, who holds a research fellowship at the same Institute. Both papers dealt specifically with aircraft noise and vibration.

Prof. Richards began by emphasizing that the primary function of the human ear is communication, and he defined 'noise' as everything which is heard and which hinders communication. He allowed a fairly wide definition of communication and illustrated with several amusing examples how the labelling of a given sound pattern as 'noise' (that is, 'annoying') depends very largely on circumstances and will vary greatly from one individual or community to another. The annoyance caused by jet aircraft noise is, he said, virtually impossible to establish in scientific units and can only be assessed by the reactions of the population in areas irradiated by the noise. He described the establishment of empirical limits of acceptable noise around airports, based on the incidence of complaints by individuals and organized groups living nearby, and cited American surveys of aircraft noise and public reaction to it during operation of piston-engined aircraft from Idlewild Airport, New York (before the introduction of jet traffic). These surveys were used to establish a figure of 107 decibels as the maximum tolerable overall noise-level, measured at ground-level in the open air.

However, Prof. Richards continued, when jet aeroplanes began to fly overhead producing 107 decibels of noise on the ground, it was soon obvious that this figure was no longer acceptable—owing to the different quality of the noise from jet engines. Prof. Richards then digressed to explain the decibel scale of sound pressure measurement—related to the logarithmic response of the human ear to mean square sound pressure—and went on to stress the fact that the disturbance produced by noise depends very much on the frequency distribution of the sound. This is partly due to the non-linear frequency-response of the human ear, and, in practice, it is found that noises of high pitch are considerably more annoying than equally intense noises of relatively low pitch. Prof. Richards showed the meeting curves of equal subjective loudness, together with curves of equal 'noisiness' (annoyance) for pure tones, obtained by American workers in laboratory studies, and he pointed out that the latter curves were, in effect, weighted against the higher frequencies.

The reason for the greater annoyance produced by the jet aircraft (at a given overall sound pressure-level) lies in its emitting a higher proportion of its

total noise at high frequencies. For example, jet aircraft noise spectra show the highest levels in the frequency-band 600–2,400 c./sec., as against the band 75–300 c./sec. for the propeller aircraft. Prof. Richards described the concept of the 'perceived noise-level' (quoted in *PN* decibels) and its derivation using the subjective 'equal noisiness' data to transform physical sound pressure measurements. The determination of perceived noise-level allows comparisons between noises of differing spectral quality. A criterion of acceptability can therefore be established for jet noise, based on information regarding other types of noise from industrial sources and piston-engined aircraft. It turns out that the acceptable 107 decibels for propeller aircraft at Idlewild is equivalent to 111 *PN* decibels, which is now the standard accepted by the American authorities and to which jet aircraft must conform in populated areas around that aerodrome.

Prof. Richards then described the probable need for revision and modification of currently accepted *PN*-levels as jet operations became more extensive and the characteristics of jet aircraft and their flight envelopes altered. Present methods of minimizing jet noise include the fitting of noise suppressors and the practice of throttling back the engines when passing over built-up areas during the climb. This of course lengthens the climb and, while reducing the intensity of the local noise nuisance, spreads it over a wider area. Prof. Richards recalled that the current standards of acceptable noise were based on reactions to the worst quartile of propeller aircraft operating over a fairly narrow zone, and that jets would cause a more widespread disturbance. (At the present time, however, the worst annoyance is caused by jet airliners frequently breaking the rules for noise reduction on take-off.)

It is anticipated that the number of jet aeroplane movements at London Airport will increase some eight-fold over the next decade or so, involving not only a very high frequency of take-off during the day but also the introduction of more night operations. Prof. Richards considered some of the implications of these trends for the 111 *PN* decibels-limit. It has been found that, when the incidence of complaints from the surrounding population is related to the number of take-offs at different times of day, proportionally more annoyance is caused by noise during the evening hours of wireless and television entertainment and bed-going. It has been suggested, therefore, that a 10 *PN* decibels reduction in allowable noise must be specified for night operations. It will also be necessary to consider the duration and frequency of occurrence of aircraft noises, and some further reduction in the day-time standard may become obligatory as jet traffic grows heavier.

It appears that quite a high proportion of complaints arise from the landing of jet airliners rather than their taking-off and that in many cases (80 per cent in one survey) people who expressed annoyance revealed, directly or indirectly, some element of fear of aircraft crashes. The pattern of noise on landing is different from that on take-off and is probably more alarming, since the aircraft passes lower over the house-tops, the onset of noise is sharper and the sound spectrum often contains discrete

frequency spikes due to compressor whine. A typical jet aircraft throttled back for landing might show a spike of some 15 *PN* decibels amplitude superimposed on the random noise spectrum at about 2,000 c./sec. It is found that noise containing discrete frequency spikes is more disturbing and would require a lower *PN* decibel figure as the maximum acceptable. The 'annoyance penalty' in the example cited would be of the order of 6 *PN* decibels; but Prof. Richards recommended caution in interpreting such figures, since the estimates of penalty due to discrete frequencies are based on laboratory experiments using 'white' noise, whereas the practical *PN* decibel limit is based on studies of propeller aircraft noise which is itself made up of discrete frequency sounds.

Prof. Richards amplified some of the above points in replying to questions asked in discussion, during which a number of speakers expressed alarm at the prospect of the worsening noise nuisance brought about by jet operations. He agreed that what is urgently needed are extensive and well-controlled social surveys of the noise problem. Speaking on the threat of sonic bangs produced by supersonic transport aircraft, Prof. Richards said that, during a typical supersonic flight, free air pressure jumps of the order of 1 lb./sq. ft. must occur over the majority of the flight path. The nuisance value of such bangs was not at all certain but may be great, affecting large populations if supersonic airliners were to fly overland as well as overseas routes. The problem, again, was one of annoyance and its assessment. Individual reactions to impulsive noise were likely to be very variable. The approach was to determine experimentally the limiting tolerable amplitudes of pressure jump, using realistic samples of people in rather the same way that thresholds of annoyance by continuous noise can be determined in the laboratory and in the field. Prof. Richards felt that, while the aeronautical engineer and the acoustician can do much to minimize aircraft noise at source and in transmission, there is still an urgent need for human data which must be provided by the experimental psychologist and the social scientist.

Aircraft noise disturbs a large population outside the aircraft, whereas mechanical vibration as an environmental factor concerns only the people inside it. Published work on the physiological actions of vibration is accordingly much smaller in quantity, less well known, and of less general interest than that on noise and hearing. The paper by Flight-Lieut. J. C. Guignard and Mr. A. Irving described current research at the Royal Air Force Institute of Aviation Medicine, Farnborough, on the effects of very low-frequency vibrations on man. This is, in the first instance, a problem of military aviation. Aircrew can be violently jostled in high-speed flight through turbulence and, again, disturbing intensities of more or less periodic vibration can occur in some types of aircraft—notably helicopters. In civil aviation, it has been predicted that vibration will be a potential nuisance to the passengers and crew in supersonic airliners. These aircraft may have natural modes of oscillation at very low frequencies, easily excited by gusts and being poorly damped at the great altitudes at which supersonic flight is to be made.

After reviewing briefly the biological actions of mechanical vibration (which are in many cases fairly narrowly frequency-dependent), the authors went on to explain the approach they have adopted in their present field. Although in-flight studies of reactions

to turbulence and experiments using dynamic flight simulation have their attractions, the authors favoured the study of human frequency-response to simple sinusoidal vibration. Some reasons were given for this approach, including ease of interpretation and generality of application of the results. The frequency band selected for study was the infra-sonic region (that is, below about 20 c./sec.) in which are excited major aircraft structural modes of vibration, as well as physical resonances in the human body. The lower limit of the band studied was 2 c./sec.

A method of conducting resonance search tests on the human body was described in some detail. One feature which had not been adopted in previous work was careful standardization and control of the subjects' posture (as well as other conditions of vibration) during the tests. Acceleration resonance was measured in seated men at forcing frequencies of approximately 2.4, 4.8 (the dominant response) and 13 c./sec., the latter being detected only as a phase resonance between seat and head. So far, the results showed fair agreement with those of other workers, but the investigation was taken a step further by examining the influence of some physical variables in the conditions of vibration on the resonant response of the body. The influence on resonance of body size, force of vibration (that is, acceleration-amplitude) and muscular tensing were examined and it was found that, while the effects of the first two named were small, tensing modified considerably the man's dynamic response. The tensing manoeuvre, in effect, increased both the damping and the stiffness of the body, reducing the dynamic amplification at resonance and increasing the dominant resonant frequency to nearly 6 c./sec.

The paper ended with an account of a simple experiment of more direct practical interest concerning the degradation of visual and visuo-motor performance by whole-body vibration. Performance was measured in four subjects doing two simple tasks during vertical sinusoidal vibration applied through the seat, the test material remaining at rest. The measure of performance used was the time taken to complete a number of replicates of each task. Five frequencies of vibration were applied, in half-octave increments from 2.4 to 9.5 c./sec. at a constant acceleration-amplitude of 0.25*g*. The presentation of conditions was randomized and performance during vibration was compared with that at rest. Vibration hindered the subjects, and the worst performance in each task was measured at 3.4 c./sec. (which is a rather lower frequency than that of the dominant physical resonance in the body). The authors concluded—very tentatively—that the degradation of visual performance in this experiment was related to the velocity-amplitude of vibration at the subject's head. It was incidentally pointed out that breaking down of fixation of a static target by the eyes during whole-body vibration occurs at about 2 c./sec.

Flight-Lieut. Guignard agreed with comments made in discussion to the effect that vertical vibration was only one component of the acceleration pattern of an aircraft in flight, and also stated that different patterns of resonance could be elicited in the body by, for example, transverse excitation. Most work has been done on vertical vibrators as a matter of custom and convenience, and because the vertical components of low-frequency aircraft vibration were considered to be particularly important.

J. C. GUIGNARD

OBITUARIES

Prof. E. M. Killick

PROF. ESTHER MARGARET KILLICK died on May 31. Her sudden death ended an active and productive professional life, during which she made significant contributions to physiological knowledge, participated widely in academic administration, and was held in high esteem by students and colleagues alike.

Esther Killick came of a medical family, and after her education at Leeds Girls' High School, proceeded to the University of Leeds. Having obtained her medical qualifications, she began her professional career as an investigator to the Safety in Mines Research Board. During this appointment she demonstrated her clinical ability by obtaining the membership of the Royal College of Physicians at the first attempt, without having previously held a house appointment. During her association with the Mines Research Board she came into contact with J. S. Haldane and his work, and her interest in respiratory problems persisted up to the time of her death, when she was still actively engaged in research in respiratory physiology. This interest had a basis in the feeling that her best contribution to medicine would be in the study of the etiology of human respiratory disease, especially in mining and other industries.

Following the work in Leeds, she was appointed lecturer in industrial medicine and hygiene in the University of Birmingham in 1935. Three years later she was appointed lecturer in applied physiology in the London School of Hygiene and Tropical Medicine, and at the same time married Prof. A. St. G. Huggett, professor of physiology at St. Mary's Hospital Medical School. She had two daughters, born in 1940 and 1945. After spending four years at the London School of Hygiene, on the retirement of Prof. Winifred Cullis from the Sophia Jex-Blake chair of physiology in the Royal Free Hospital School of Medicine, she was appointed to this professorship. She thus came to control a department in a school which has a notable record of pioneering educational achievements, and which has, in the past, fostered the cause of education in the sciences for women, when other schools maintained an attitude of indifference, or even of open hostility.

Prof. Killick entered into the problems of her professional appointment with great energy and evolved a well-balanced and highly efficient department, at the same time actively pursuing her own research interests and entering very fully into administrative work. In the course of these activities she contributed, over a long period, research work of high quality, particularly on the effects of carbon monoxide on man and animals. This particular aspect of respiratory physiology and pathology became more and more her special interest in medicine. She was the first to show that the mouse and man acclimatize to carbon monoxide differently, and that the latter does so by the pulmonary epithelium developing the power of actively inhibiting the passage of carbon monoxide from the lungs into the blood, thereby allowing more oxygen to be taken up than would occur if both gases entered by diffusion. This active intervention by the epithelium of the

lung explained in an unexpected way the phenomenon which Haldane some years previously had attributed to active secretion of oxygen into the blood. In fact, as Esther Killick showed, Haldane was right in attributing an active role to the pulmonary epithelium, but it was not active transport of oxygen. Her special knowledge in this field was sought widely, both in Great Britain and in the United States, particularly by the U.S. Air Force. She served on various committees concerned with this aspect of physiology, both during and after the War, with the Royal Navy and the Medical Research Council.

In 1953 she worked as a visiting professor in the Department of Medicine at Johns Hopkins Medical School with Dr. R. L. Riley and Dr. Joseph Lillenthal.

She took an active and exceedingly useful part in the administrative work of the University of London. In this she showed exceptional powers of quick and logical thought, and the ability to eliminate the irrelevant and the redundant. She was, in consequence, a most effective chairman, and occupied this position on the Board of Studies in Physiology, and the Board of Pre-Clinical Studies. She was a member of the Board of the Faculty of Medicine, and her advice and opinion were particularly valued on the Senate Committee on Colleges Overseas in Special Relation. Perhaps her work on the latter was her most outstanding contribution to the University, since she participated in the establishment of the Preclinical Departments in the Colleges of Ibadan and the West Indies, and on various occasions served as examiner or visiting representative of the University of London. She also served on the Committee of the Central Research Funds of the University and on the Special Advisory Board on Biophysics.

These various activities illustrate her energetic participation over the whole field of academic work, but they cannot convey the outstanding characteristic of Esther Killick. This was the possession of a quiet manner and a kindly and pleasant disposition which accompanied a keen and quick intelligence and a character of exceptional resolution and determination. These characteristics were discernible in all she did and, in addition, those of her colleagues who have participated in university examinations with her will always remember her quiet approach to the candidates, the kindly appreciation of their problems, and the scrupulous accuracy of assessment of their work.

Esther Killick was guided by certain principles, and one of these was the belief that women, just as well as men, could contribute to society and to a profession by reason of their intrinsic worth; and that they could pursue an active career and simultaneously bring up a family. In both of these she achieved success.

In her work she upheld the traditions of the Royal Free Hospital School of Medicine, the School which appointed in the person of her predecessor the first woman professor of physiology in the University of London. Over the period of nearly twenty years during which Esther Killick worked at the Royal Free, she was held in esteem and affection by her students, her staff and by a wide circle of colleagues.

W. BURNS

Mr. L. J. Goldsworthy

LEONARD JAMES GOLDSWORTHY was head boy of Ripon Grammar School (1910) and won an Exhibition to Magdalen College, Oxford. Here he became a pupil of T. S. Moore and after graduation (1913) carried out research under the supervision of W. H. Perkin, jun. He took part in College laboratory teaching at Christ Church and Queen's College.

At the early age of twenty-four he became professor of chemistry at the Victoria College of Science, Nagpur, but his scientific work and teaching naturally suffered in the early years of the First World War because of his keen attention to military duties. During 1917-20 he saw active service in Egypt and Palestine as an officer of the Deccan Horse, 16th Cavalry, and held several administrative posts. In later years he continued military activities and during 1933-35 was commanding officer of the 6 (Burma) Batt., U.T.C. Still later he served in the Second World War in the Home Guard in Oxford.

During 1917-22 Goldsworthy held various posts as inspector of schools and deputy or assistant director of public instruction, but in 1923 returned to chemical teaching and research as lecturer at University College, Rangoon; he became officiating professor of chemistry in 1931, retiring in 1935.

While in Burma, Goldsworthy held many official advisory posts and, as was ever his wont, did all that was possible to promote the welfare of his students. He was a warden of one of the university halls of residence and a member of the governing bodies of several university colleges in Burma.

After leaving Rangoon he returned to Oxford and undertook research on intermediates in contemplated synthesis of penicillin and other topics related to

natural products, as well as more general fields such as the Leuchs synthesis of polypeptides, orientation of substitutions in benzene derivatives and certain molecular re-arrangements of interest in relation to the chemistry of quinamine. Some of this work was unfinished. In 1937 he found that the Leuchs reaction applied to *d*- or *l*-alanine gave a polypeptide similar to that from glycine, very sparingly soluble and of high molecular weight. But *dl*-alanine under the same conditions gave a water-soluble product of a quite different type. The analyses of ester end-groups indicated a low molecular weight, but it was felt that this required confirmation and other interests supervened.

Later he received a University appointment as senior research assistant to the Waynflete Professor. In this capacity his long experience in the East was turned to very good account, and with characteristic unselfishness and generosity he gave invaluable personal help to many beginners in research and to others who encountered special difficulties. Goldsworthy's own technique at the bench was very neat and his practical example most effective. To overseas students in particular he was not only guide and philosopher, but also friend. Many of them enjoyed his hospitality and that of his wife.

After 1955, one of his major interests was the development of gas-liquid chromatography and, though he retired in 1958, he continued to assist the teaching work at the Dyson Perrins Laboratory and delivered lectures in the academic year 1959-60.

He was a man of great personal charm, a most sincere scientist and a devoted teacher. In 1927, he married Rose Cawthorn and there are two sons.

ROBERT ROBINSON

NEWS and VIEWS

Royal Society: Medal Awards

THE following awards of medals have been made by the President and the Council of the Royal Society: *Copley Medal* to Sir Harold Jeffreys, formerly Plumian professor of astronomy in the University of Cambridge, for his distinguished work in many branches of geophysics, and also in the theory of probability and astronomy; *Rumford Medal* to Dr. A. G. Gaydon, Warren Research Fellow, for his distinguished work in the field of molecular spectroscopy and particularly its application to the study of flame phenomena; *Davy Medal* to Prof. J. M. Robertson, Gardiner professor of chemistry and administrative head of the Chemical Laboratories in the University of Glasgow, for his distinguished pioneering work on analysis of crystal structure, especially of organic compounds; *Darwin Medal* to Mr. E. J. H. Corner, reader in plant taxonomy in the University of Cambridge, for his distinguished and strikingly original botanical work in tropical forests; *Hughes Medal* to Dr. J. L. Pawsey, assistant chief of the Division of Radiophysics of the Commonwealth Scientific and Industrial Research Organization, Australia, for his distinguished contributions to radio astronomy both in the study of solar and of cosmic radio emission.

National Institute of Sciences of India: Awards

At the annual general meeting of the National Institute of Sciences of India held on October 7, the following awards were announced: *Shanti Swarup Bhatnagar Gold Medal* 1959 (for applied sciences), to Dr. Atma Ram, director of the Central Glass and Ceramic Research Institute, Calcutta, for his outstanding contributions to the development of technology and creating a science consciousness in the glass and ceramics industry in the country; *Chandra Kala Hora Memorial Medal* 1960 (for contributions to the development of fisheries in India), to Sri Hiralal Chaudhuri, research officer (fish breeding), Central Inland Fisheries Research Station, Barrackpore, for his contributions towards induced breeding in carp.

Mining at Leeds: Prof. J. T. Whetton, O.B.E.

PROF. J. T. WHETTON, who has recently retired from the chair of mining in the University of Leeds, has had a distinguished academic and military career. After gaining early mining experience in the Yorkshire coalfield he served in the First World War in France and the U.S.S.R.; in 1919 he was awarded the Military Cross and the Russian Order of St. Stanislav. He resumed his mining studies at the University of

Leeds and after graduation was appointed research assistant in the Department of Mining at King's College, University of Durham, where he remained on the academic staff until 1939, becoming lecturer and then reader. During this period he was awarded the degree of M.Sc. by the Universities of Leeds and of Durham. During 1937-48 he commanded the 4th Survey Regiment, R.A.T.A., and was on active service during 1939-45 in the Balkans, the Middle East, North Africa and north-west Europe. He received the Distinguished Service Order, the Order of the British Empire, the Belgian Order of the Crown with Palm and the Belgian Croix de Guerre. Since his appointment in 1945 to the chair, the Department at Leeds has expanded steadily both in undergraduate numbers and research activities. Under his direction work in several fields, but particularly in geophysics, coal preparation, ground movement and pneumatic and hydraulic flow, has been carried out and he has contributed to nearly a hundred papers in these and other mining subjects. He was chairman of convocation for three years and was pro-vice-chancellor of the University of Leeds during 1955-57. He has been chairman of the Committee of Mining Professors of Great Britain for some years, and is at present president of the Midland Institute of Mining Engineers.

Prof. H. J. King

DR. H. J. KING, who is to succeed Prof. Whetton, had several years experience in mining and mine surveying in the South Wales coalfield before 1936 when he was awarded the David Davies Mining Scholarship and other scholarships for studies at the Treforest School of Mines and University College, Cardiff. Before he completed the course he joined H. M. Forces as a Territorial and served with the Royal Artillery and then with the Royal Engineers, specializing in tunnelling, at home and in north-west Europe. For a time before demobilization in 1945 he was staff captain at 21 Army Group with special responsibilities for establishing educational facilities for troops in preparation for their return to civilian life. On demobilization he returned to complete the mining course at Cardiff and in 1946 was awarded the joint diploma of the University College, Cardiff, and the Treforest School of Mines; in the same year he obtained the degree of B.Sc. (Eng.), London, as an external candidate and was awarded first-class honours. He was lecturer in mining in Whitwood Technical College for a year and was then appointed lecturer in mining and surveying at the University of Leeds, becoming senior lecturer in 1956, in which year he obtained the degree of Ph.D. of the University of London. In 1960 he was appointed reader in mining at Leeds. Prof. King is well known for his special interest in mine surveying and particularly for his research work in the laboratory and in the field on ground movement and mining subsidence, in which he has achieved a world-wide reputation.

C.S.I.R.O. Division of Entomology:

Mr. F. N. Ratcliffe, O.B.E.

On January 1, 1961, Mr. F. N. Ratcliffe will relinquish his position as officer-in-charge of the Commonwealth Scientific and Industrial Research Organization Wildlife Survey Section to become assistant chief of the Division of Entomology in Canberra. He will be mainly concerned with the ecological and biological control investigations that comprise a substantial part of the Division's activities. Mr.

Ratcliffe was a member of the Division of Entomology during 1937-49, working first on termites and later on stored wheat pests. Between 1941 and 1946 he served with the Australian Army Medical Corps, and was actively associated with the work of the Malaria Control Units in northern Australia and New Guinea, and with investigations on mosquito control techniques. On returning to the Division after the War, until the establishment of the Wildlife Survey Section, of which he was the first officer-in-charge, Mr. Ratcliffe acted as assistant to the chief, Dr. A. J. Nicholson, who was succeeded on his retirement this year by Dr. D. F. Waterhouse.

United Kingdom Atomic Energy Authority:

Appointments

SENIOR appointments in the Development and Engineering Group have been announced by the United Kingdom Atomic Energy Authority. Mr. P. T. Fletcher will be deputy managing director (General Management); Mr. R. V. Moore, formerly director of reactor design, will be deputy managing director (Projects); and Dr. H. Kronberger, formerly director of research and development, will be deputy managing director (Development). Mr. S. Fawcett, formerly deputy director, has succeeded Mr. Moore as director of reactor design. The Research and Development Directorate at Risley has been divided into two executive directorates. Dr. H. K. Hardy and Mr. F. W. Fenning have been appointed respectively as director of fuel element development and director of reactor technology.

Solid State Physics at Harwell

THE newly formed Solid State Physics Division at the Atomic Energy Research Establishment at Harwell, under Dr. W. M. Lomer (see *Nature*, 188, 21; 1960), is to be organized into four research groups. One group, under Dr. G. E. Bacon, will be concerned with neutron crystallography, for magnetic and structural investigations and studies in crystal chemistry. Another group, under Dr. R. D. Lowde, will use a variety of techniques, such as time-of-flight measurement and the scattering of cold neutrons, to investigate the dynamics of crystals and of spin systems. Magnetic investigations with polarized neutrons and work on various physical properties employing radioactive tracers, resonance and other techniques will form the work of a third group under Mr. A. D. Le Claire. Later a further group will be added to investigate defects in crystals. There will be opportunity for university participation in the programme.

British Shipbuilding and Research

A STATEMENT regarding the replacement of the *Queen Mary* was made on November 3 by the Minister of Transport, Mr. E. Marples, in the House of Commons and by the Paymaster-General, Lord Mills, in the House of Lords. The size, speed, accommodation and physical characteristics of the new ship will be as recommended by the Chandos Committee, and the Government also agrees with the Committee's advice that the capital cost should not exceed £30 million: up to that figure the Government and the Cunard Line will contribute in the proportion of 3 to 2, any excess being met by the Cunard Line. The ship will be owned by a separate subsidiary company of Cunard with provision to ensure that the ship and company

remain under British control. The Chandos Committee proposed that the Government's 25-year loan should carry 4.5 per cent interest, but the Government has decided that interest on the loan should be at the rate for 25-year loans which is being charged by the Public Works Loan Board when the agreement is signed. At the present interest rate of 6.25 per cent, and assuming a total cost of £30 million, the grant would amount to some £3.25 million and the loan to £14.75 million. The statement met with some criticism in both Houses. In the House of Commons, Mr. Marples maintained that the Government was not putting up much risk capital, and that according to estimates of travel for the next ten years, by the end of ten years the taxpayer would be very well covered.

Lord Alexander of Hillsborough again asked for access to the report of the Chandos Committee and Lord Mills referred to an agreement to keep confidential the mass of technical and financial information contained in the report. Lord Lucas of Chilworth, however, while agreeing that there might perhaps be good technical reasons for not producing the report, suggested that the economic survey of the prospects of trans-Atlantic travel which enabled the Chandos Committee to formulate some of its proposals could be made available, and Lord Mills undertook to look into this possibility. The proposal is to be discussed further in both Houses, but dissatisfaction with the Government decision has already been expressed on the grounds that the decision appears to have been undertaken independently of the inquiry by the Council for Scientific and Industrial Research into the shipbuilding industry, and that the report on that inquiry is also being kept secret. Incidentally, when speaking at the launching of the 9,000-ton *Olan Fergusson* on November 3, Mr. A. Cayzer, deputy chairman of the British and Commonwealth Shipping Company, suggested more research by British shipbuilders is necessary, and for that purpose smaller firms might need to amalgamate. A few large substantial companies could carry out research more easily and efficiently than a number of small units, and this applied particularly to the engine-makers.

Children's Interests In Science

To find out children's interests so that the content of a science syllabus could be devised, 141 boys and 142 girls aged eleven in St. Helens were asked to write down a list of questions in science which would interest them and which they would like to know more about. The director of education, N. F. Newbury, has summarized and analysed their replies in the summer edition of *Teaching Science*. Grouped under general headings, the topics dealt with most frequently were natural phenomena (1,186); the human body (753); how things work (718); animals other than humans (393); and in more specialized fields, floating (130); chemistry (130); light (85); inventors (48); magnetism (43). The questions occurring most frequently were of the type "How does an aeroplane fly?" (100), and "What is electricity and how is it made?" while questions such as "Why do people die?" (27), and "What is gravity?" (29), were at the other end of the scale. There was only a limited interest on questions on space: 29 questions on rockets, 10 on satellites and flying saucers and 9 on space. Some questions quoted without comment were "How far up does gravity reach? A candle wants air, so why does it go out when you blow

it? Why does heat make things expand?" By their replies the children show clearly that, at this stage, they have little enthusiasm for orthodox Nature study, but are mainly concerned with themselves and their surroundings. At this age they tend also to ask similar questions.

Historic Books on Mining and Kindred Subjects

A COLLECTION of rare and historic books owned by Mr. Robert Annan is being exhibited during November 15-December 31 at the Science Museum, South Kensington. These books deal with mining, assaying and metallurgy, mining law and mineralogy. Although mining has a long history, written records are extremely scanty, and it was not until the early and mid-sixteenth century when the works of Agricola and others were published that technical records of mining and ancillary practices became generally available. In medieval times the German miner was pre-eminent, his methods of working the ore deposits and the later treatment of the ore being much superior to those employed elsewhere. It is not surprising, therefore, that many of the rare books in the exhibition are of German origin. Books published in other countries are also to be shown: of particular interest is Gabriel Platten's "Discovery of Subterranean Treasure" of 1639, which, although having little technical merit, was the first work devoted entirely to mining to be printed in English. The oldest work on exhibition is "De Mineralibus" by Albertus Magnus (written about 1260) in the version printed at Padua about 1476 and later at Venice in 1495.

The Perkin Centenary Trust: Awards

THE Perkin Centenary Trust was established to commemorate William Henry Perkin's discovery of 'Mauveine' in 1856 and to promote technical education in all aspects of the manufacture and application of colouring matters. The Trustees offer the following awards for the academic year 1961-62: (1) *The Perkin Centenary Fellowship*, for one or two years for the purpose of higher study of any subject approved by the Trustees. Its value is £750 per annum with an additional grant of up to £100 per annum towards certain designated expenses, and is tenable, from October 1961, at any university, technical college or other institution approved by the Trustees. (2) *Two Perkin Centenary Scholarships*, each for two years, renewable at the discretion of the Trustees for one further year, to enable candidates employed in an industrial firm or other institution concerned with the manufacture or the application of colouring matters to receive an education at a university or technical college. Each award will have a value of £350 per annum. There is no means test, and a successful candidate is not debarred from receiving the whole or a part of his normal salary from his employers during his tenure of the scholarship. (3) *Perkin Centenary Trust Travel Grants*. Applications are invited from teachers concerned with the study of any aspect of the manufacture or the application of colouring matters at a university, technical college, or other institution. Preference will be given to applications from lecturers, senior lecturers and readers, or the equivalent grades in other institutions, wishing to gain experience at a similar institution or in industry overseas. Grants will be available towards the cost of travel and maintenance for periods, related to the purpose of

the visit, of from one to three months. Further information can be obtained from the Secretary, The Perkin Centenary Trust, c/o The Chemical Society, Burlington House, London, W.1. Applications for the awards must be made by May 1, 1961.

University News:

Birmingham

THE following have been appointed lecturers: Dr. P. Swinbank, C. P. Van Zyl and Dr. J. D. Dowell (physics); Dr. F. J. Emery (mathematical physics); Dr. T. S. M. Maclean and Dr. E. F. Stack-Forsyth (electrical engineering); K. Foster (mechanical engineering); Dr. G. W. Rowe (industrial metallurgy); Dr. G. M. Bennison (geology); Dr. D. A. Wilkins (botany); Dr. J. M. Webber (chemistry). The appointments to fellowships are as follows: B. W. Petley (physics); H. R. Shaylor (Staff Fellow in nuclear physics); T. W. Preist and T. F. Tuan (mathematical physics); B. Cockayne and Dr. N. Pessall (physical metallurgy); D. J. White (engineering production); D. G. Parsons (S. C. Johnson Research Fellow in the Department of Chemistry). The above appointments took effect on, or before, October 1.

Edinburgh

THE following appointments to lectureships have been announced: B. I. Davies (bacteriology); Dr. P. C. Jocelyn (senior lecturer in biochemistry); Dr. L. G. Plaskett (biochemistry); M. Jacobson (physiology); Dr. A. L. Bartlett (veterinary pharmacology).

Hull

RECENT appointments to lectureships included: Dr. D. W. G. Ballentyne (physics); Dr. J. Friend (botany); S. C. Kapoor (philosophy). Research fellowships have been given to Dr. P. Bruck (chemistry) and Dr. A. Richmond (chemistry).

Leeds

AMONG the recent appointments to lectureships are the following: Mr. P. Kelly (metallurgy), Mr. C. Mack (textile engineering) and Mr. J. R. Proud (agriculture). Dr. D. F. Horler has been appointed as Research Fellow in the Department of Leather Industries and Dr. W. E. Seeds in the Department of Biomolecular Structure. The titles of emeritus professor have been conferred on Prof. P. J. Moir, on his retirement from the chair of surgery, Prof. E. A. Spaul, on his retirement from the chair of zoology, and Prof. J. T. Whetton, on his retirement from the chair of mining.

London

DR. B. J. MASON, Warren Research Fellow of the Royal Society, has been appointed to the University chair of cloud physics tenable at the Imperial College of Science and Technology from October 1, 1961. Dr. S. Cohen, of the National Institute for Medical Research, has been appointed to the University readership in immunology tenable at St. Mary's Hospital Medical School.

Dr. D. R. Laurence, senior lecturer at University College and University College Hospital Medical School, has been appointed to the readership in pharmacology and therapeutics tenable at the College and School; the title of reader in tropical hygiene in the University of London has been conferred on Dr. B. B. Waddy in respect of his post at the London School of Hygiene and Tropical Medicine.

Announcements

THE Keith Prize for the period 1957-59 of the Royal Society of Edinburgh has been awarded to Dr. J. B. Tait, Department of Agriculture and Fisheries for Scotland Marine Laboratory, Aberdeen, for his paper entitled "Recent Investigations in the Faroe-Shetland Channel", published in the *Proceedings* of the Society during the period of the award and for his work in the general field of oceanography.

SIR RICHARD RAMAGE has been appointed Commissioner to examine the present arrangements for localization in the East African Posts and Telecommunications Administration and certain other services of the East Africa High Commission, and to make arrangements for accelerating the process. In particular, he is to consider an extension of the 'in-service training scheme' and qualifications at present required in all grades in which posts are held by expatriate officers.

DR. FRED LESTER, head of the Department of Science at Hatfield Technical College, has been appointed principal of the College of Further Education, Loughborough, and will take up his duties on January 1. Dr. R. F. Robbins, formerly of Nottingham Technical College, and at present senior lecturer in organic chemistry at Hatfield, has been appointed head of the Department of Science as from January 1, 1961.

BESIDES a list of members, with an alphabetical index, and a list of members elected on May 11, the Records of the American Academy of Arts and Sciences, 1959-60, includes lists of officers and committees for 1960-61, the statutes, records of meetings, 1959-60, and the reports presented at the annual meeting on May 11, 1960 (Pp. 128. Boston, Mass.: American Academy of Arts and Sciences, 1960).

THE Institute of Physics and the Physical Society is organizing a conference on "Physics of Polymers" at the University of Bristol during January 10-12. Further information can be obtained from the Secretary, Institute of Physics and Physical Society, 47 Belgrave Square, London, S.W.1.

THE Department of Chemistry, Purdue University, in co-operation with the Office of Naval Research, is organizing a symposium on "Nitro Aliphatic Chemistry", to be held at Lafayette, Indiana, during May 25-26, 1961. Emphasis will be placed on polynitro aliphatic compounds. Those wishing to contribute papers should send abstracts to Prof. Henry Feuer, Department of Chemistry, Purdue University, Lafayette, Indiana, from whom further information can be obtained. Abstracts must be received not later than February 1.

A SYMPOSIUM on "Plant Resources of the Middle East and South Asia for the Pharmaceutical Industry and Rauwolfia", organized jointly by the Government of Pakistan, the Unesco Middle East Science Co-operation Office and the Unesco South Asia Science Co-operation Office, will be held at the North Regional Laboratories of the Pakistan Council of Scientific and Industrial Research, Peshawar (Pakistan), during December 6-14. Further information can be obtained from the Unesco South Asia Science Co-operation Office, 21 Curzon Road, New Delhi, or the Indian National Commission for Unesco, Ministry of Education, Government of India, New Delhi.

THE INSTITUTE OF BIOLOGY

THE tenth anniversary of the foundation of the Institute of Biology was celebrated by a dinner held in the restaurant of the Zoological Society of London on January 8, 1960.

It may be recalled that the first general meeting of the Institute was held at King's College, London, on January 5, 1950, when more than 150 biologists were present, representing most branches of the subject. This meeting, however, was only a culmination of more than three years activity (see *Nature*, 168, 131; 1951). A council of fourteen members was elected, with Dr. E. Hindle as president, Prof. J. F. Danielli as honorary secretary, and Dr. R. J. C. Harris as honorary treasurer. Rules of membership were drawn up, and an office was established in the British Medical Association House, Tavistock Square, with a general secretary and staff. The membership reached about 500 by the end of the year and has steadily increased so that by the end of 1959 it numbered 2,250, with 260 overseas members.

Each year the Institute has held a symposium on some subject of general biological interest and published the papers and discussions. The first symposium in 1950 was on "Biological Hazards of Atomic Energy", and the topic for 1960 was "Biology of Space Travel". Freezing and drying, biology of deserts, biology of the sea, numbers of man and animals, biological aspects of the transmission of disease, the biology of ageing, the biological productivity of Britain, the effects of pollution on living material, and problems arising from the control of pests and diseases indicate the wide range of topics which have been discussed at successive meetings; and the records of these symposia are of considerable value to students in these respective fields.

The Institute's widening activities necessitated larger premises, and in 1955 a move was made to the present quarters at 41 Queen's Gate, London, S.W.7. At the same time, nine local branches have been founded: six in Britain, one in Northern Ireland, another in Eire, and one in Malaya. These local branches hold meetings independently of the central organization.

The Institute represents the views of biologists on various national and local bodies concerned with technical education, and played an active part in

promoting the scheme for endorsed certificates, which is now firmly established with courses in some dozen centres. The Ministry of Education has now joined the Institute in endorsing certificates; and the Scottish Education Department, with the co-operation of the Institute of Biology, has instituted a National Certificate in Biology.

The Institute publishes a quarterly journal containing news of general interest to biologists, as well as articles on broad topics and book reviews. One of its publications, "Biology as a Career", is now in its third edition; in addition, advice on this subject is given to student members, parents, youth advisory officers and teachers. Also two surveys on salaries were undertaken, during 1953 and 1956.

The Institute maintains an appointments register for the use of members seeking advice on potential employers and vacancies, a service of especial value to overseas members. It also publishes a list of full-time consultants on biological subjects, including a list of topics for which the services of occasional consultants can be obtained. The Institute also maintains an information service for the use of members, Government departments, firms and the general public, and is consulted on a wide range of biological subjects.

On various occasions the Council of the Institute has made representations of their views to various Ministers of State on matters affecting the development of biological research. Through the medium of the Parliamentary and Scientific Committee, assistance is given to keep members of Parliament informed of the biological background to such problems as food supplies, ageing, Colonial research, pollution, etc.

The officers of the Institute have been selected with the object of obtaining as wide a representation as possible of the various branches of the subject. The office of president, restricted to two years duration, has been held successively by Dr. E. Hindle, Prof. F. E. Fritsch, Sir James Gray, Prof. W. H. Pearsall and Dr. A. S. Parkes. The honorary secretaries have been Prof. J. F. Danielli, Dr. G. E. Fogg and Mr. H. J. Bunker; and honorary treasurers, Dr. R. J. C. Harris, Dr. N. E. Hickin and Mr. W. V. Harris. The general secretary, Mr. D. J. B. Copp, has served the Institute since 1951, having previously been assistant-secretary of the British Association.

NUCLEAR SCIENCE IN THE MIDDLE EAST

IT might be thought a bold experiment to hold a nuclear science conference in an area which is only just beginning to make progress in this field; nevertheless, the symposium held in Hamadan during July 6-18 was an undoubted success.

The symposium was organized by the CENTO (Central Treaty Organization) Institute of Nuclear Science in Tehran (see *Nature*, 186, 513; 1960), and all ten of its scientific staff took part. The total number of participants was about sixty, as follows:

France	1
Iran	more than 30*
Pakistan	8*
Turkey	2
United Kingdom	12*
United States	2
United Nations observers	2

* Including CENTO Institute staff.

The French and United Nations participants were experts on various missions in Iran. Delegates' expenses were met from CENTO funds, from the

funds of the Governments concerned, and from other sources.

The symposium was opened by Dr. T. Ziai (Under-Secretary, Ministry of Industries and Mines) on behalf of the Iranian Government, and by the Governor of Hamadan. Thereafter there were nineteen working sessions, including four general discussions, on a wide range of nuclear science topics. The proceedings were informal, and no record was kept; this no doubt contributed to the freedom and liveliness of discussion.

Perhaps the most valuable feature of the symposium was its impact on the nuclear science policies of the CENTO countries. To this end, many of the papers took the form of surveys in which the authors assessed what lines of work might be profitable in their particular field, and what they might involve in facilities and training. For example, Dr. D. I. Page, of the CENTO Institute, considered the application of isotopes to water-flow problems, with special reference to conditions in Turkey. He listed ten problems which had been proposed by the Hydraulics Research Laboratories in Ankara. Of these, four appeared impracticable for such reasons as the large amount of radioactivity involved; two others appeared of doubtful feasibility; and four others, estimation of suspended matter in flood water, detection of seepage points in irrigation channels, movement of underground water, and analysis of cement by radioactivation, were worth pursuing.

Another paper providing useful guidance to countries considering new programmes was that on mutation-breeding in agriculture, by Dr. H. J. Curtis of the Brookhaven National Laboratory. He emphasized the necessity of growing very large numbers of plants in such work; the fact that the variations produced by radiation can also be produced by more conventional means; the need for a lengthy programme of orthodox plant-breeding before a commercially valuable variety can be derived from a radiation-produced mutant; and the meagre results to date in terms of new commercial varieties. Nevertheless, the fundamental aspects of the work fully justify continued effort.

Further papers in the same category were those on prospecting for radioactive minerals, on running a fall-out laboratory, on the use of carbon-14 in biochemistry, and on establishing a medical radioisotope clinic. There were also general discussions on the potentialities of radioisotope applications in the CENTO region, on their applications in the oil industry, and on atomic energy and public health.

Iran, as the host country, naturally sent the strongest delegation to the symposium, and this gave an opportunity for direct discussion of her nuclear science programme. Prof. A. A. Azad, who is in charge of the Tehran University Nuclear Centre, gave a general account of the programme, which includes a 5-MW. swimming-pool type reactor to be operating in 1962; and Dr. A. A. Sheibani described the Iranian radioactive prospecting project. The discussion which followed ranged over such fundamental issues as the possible uses of a large research reactor, and the value to the region of some of the larger nuclear instruments. The interest aroused was such that both the Pakistani and Turkish delegations expressed a desire for similar international discussions in their own countries.

Other topics at the symposium included reactor instrumentation, waste disposal and recent applications of radioisotopes in medicine, besides various research reports on nuclear physics and on applications of radioisotopes in botany and entomology.

The choice of Hamadan, a quiet, historic town, as the venue of the symposium, rather than Tehran, was something of a novelty to the Iranians, but was much appreciated by all the delegates on account of the relaxed atmosphere and opportunities for informal contacts that it provided. The local authorities contributed to this by their welcome and by their generosity in providing a meeting place, excursions and other amenities. As a final charming gift they gave each delegate a framed picture of a scientist of former days, Avicenna, whose home town was Hamadan.

H. A. C. McKAY

CONVECTION IN METEOROLOGY

THE subject of "Convection" was chosen as the topic of the symposium for the first day of the Royal Meteorological Society's summer meeting held in the Electrical Engineering Department, Queen's College, Dundee, on June 30. This was the first meeting of the Society ever to be held in Dundee, and was to be followed on the next day by a symposium on "Agricultural Meteorology" (see *Nature*, 187, 995; 1960). The president of the Society, Dr. J. M. Stagg, took the chair.

The opening speaker was Dr. F. H. Ludlam of the Imperial College of Science and Technology who reviewed the subject of convection in the atmosphere. This is a phenomenon which ranges in scale from the currents associated with fair-weather cumulus to those in the large thunderstorms which result in extensive flooding. Whereas the dynamics of the smaller currents are broadly understood as circulations associated with rising bubbles or columns of warm air, the dynamics of thunderstorms, or for that

matter, the precise physical processes involved, are not so well understood. The Bénard convection cell pattern, for which a theory exists, does not seem to occur frequently in the atmosphere, although recent photographic evidence from an American weather research rocket shows a regular pattern of 'groups' of cumulus. The most satisfactory method of forecasting the extent of cumulus development still seems to be that based on the old 'parcel' theory, where the air is assumed to form into bubbles or 'parcels', which break away from the surface and rise adiabatically through the environment until a layer sufficiently stable to prevent further penetration is reached. This method entirely neglects any modification of the environment, such as subsidence warming, and leads to little real understanding of the dynamics of the process.

The difference between a large cumulus extending to, say, 15,000 ft., and a cumulonimbus, with its associated characteristics of hail and lightning, seems

to be more than an enlargement of scale of the same process. A completely new physical factor seems to be involved resulting in up-currents which may be as large as 80 m.p.h. and horizontal currents of up to 60 m.p.h. Radar observations made by workers from the Imperial College of Science and Technology and the Meteorological Office have shown air to move into the base of such a storm at 60 m.p.h., and maintain this speed while passing vertically up through the storm, flowing horizontally out of the top at a height of 7 or 8 miles. The kinetic energy of such a system extending over a horizontal region of about 20 square miles is 100–1,000 times that of a typical large cumulus producing a moderate rain shower. The exceptional rate of growth to a thunderstorm of this size from the typical large cumulus usually occurs after rain has started falling. A physical feature of these thunderstorms which indicates the great energy of the up-draught is the exceptional size of hailstorms produced, which may be as large as golf balls. The latent heat of fusion released during their growth may be an additional source of energy, acting as a kind of booster to convection originated by surface heating.

Many of the vigorous thunderstorms affecting southern England have their origins over northern France and are propagated, rather than simply carried, in the upper-wind system. A strong-wind shear is always associated with these storms and they exhibit a well-defined anvil of cirrus cloud.

Fig. 1. Temperature fluctuations observed above a heat source in water. Rate of heating of plate = 40 W.

Dr. Ludlam was followed by Mr. C. Dixon of Queen's College, Dundee, who described an experiment he had performed on the initiation of convection currents in water. A semi-circular copper plate 5 cm. in diameter with an embedded electrical heating element was placed on the bottom of a tank of water with the straight edge adjacent to the 'Perspex' front of the tank. Thermocouples were set on to this face at intervals of $\frac{1}{2}$ cm. above the heater and temperature variations at these levels recorded on a Cambridge 6-channel oscillograph. A tracing of a typical recording is shown in Fig. 1. A period of about 10 sec. (depending on the rate of heating) elapsed before any temperature fluctuation was observed, and then an initial pulse travelled past the thermocouples in succession, followed by further pulses at fairly regular intervals of 2–3 sec. On switching the heater off, the pulses died away after a few seconds. It is hoped eventually to photograph tracers to determine the

Fig. 2. Absorption of energy by gravity waves at an inversion.

$$\epsilon = E/r^2 g \Delta \rho, v^2 = \frac{1}{2\pi^2} \cdot \frac{g r \Delta \rho}{\omega \rho}$$

E = energy absorbed by waves, ρ = density of lower layer, $\Delta \rho$ = density deficit of the upper layer, r = radius of bubble, ω = velocity of rise

velocity distribution in these currents and associate this with the temperature variations.

The third contributor to the symposium was Mr. F. W. G. Warren of the University of Sheffield, who explained a mathematical theory he had developed to determine what proportion of the kinetic energy of ascent of a thermal bubble or column was used in the production of gravity waves at an interface when the bubble or column penetrated a more stable layer. His results showed that such wave production was a maximum when the temperature of the rising column was about midway between those of the upper and lower layers near the interface, that is, such that the bubble was buoyant with respect to the lower layer, but not with respect to the upper. The dependence of the gravity wave-energy on the velocity of the bubble and its size is shown in Fig. 2.

The closing speaker was Dr. R. P. Pearce of Queen's College, Dundee, who explained a theory he had worked out for the development of sea-breezes and which also, with only slight modification, applied to the development of convection currents. The fundamental problem in both these cases is to solve the equations of heating and motion to give the velocity and temperature distributions at any time resulting from a given rate of heat-input. In the case of the sea-breeze this means predicting the time of onset of an onshore wind, and its strength, at any point inland from the coast, given the rate of heating well inland. In the convection problem it means being able to calculate the rates of growth of currents of various sizes from

Fig. 3. Sea-breeze development. Surface velocity in km. per hr. Rate of heating $3^\circ \text{C. per hr.}$ beyond 2 km. inland, decreasing towards the coast. Atmosphere initially static and isothermal

Fig. 4. Development of a thermal. Velocity in m. per sec. Atmosphere assumed initially static with dry adiabatic lapse-rate. Rate of heating approximately $1^{\circ}\text{C. per } 3\text{ min. up to } 25\text{ m.}$, $1^{\circ}\text{C. per } 6\text{ min. at } 37.6\text{ m.}$ and zero above 50 m.

the known rate of heating that produces them. In both problems the velocity and temperature distributions can be taken as two-dimensional, assuming no variations parallel to a long straight coastline in the case of the sea-breeze, and symmetry about a vertical axis in the case of a convection current. Nevertheless, the mathematical problem is still very complex, involving frequent integrations of Poisson's equation in two dimensions, a time-consuming process even for an electronic computer. A further simplification was therefore made assuming the form of the vertical distributions of velocity and temperature for the sea-breeze, and the radial distributions for the convection current. These assumptions are not unreasonable when the vorticity distribution is elongated, in this case horizontally for the sea-breeze and vertically for the convection current. The result, after introducing boundary conditions and integrating the equations to include the assumed distributions, is to eliminate one of the space variables, leading to a single partial differential equation to be solved for the surface (or axial) velocity u as a

function of distance from the coast (or ground) x and the time t . This equation is of the form:

$$\frac{\partial^2 u}{\partial t^2} + a \frac{\partial^2 (u^2)}{\partial x \partial t} + b \frac{\partial^2 (u^2)}{\partial x^2} = F(x, t)$$

Here a and b are numerical constants with values depending on the assumed profiles of velocity and temperature. $F(x, t)$ is the horizontal gradient of the heating-rate in the case of the sea-breeze and can be taken as zero everywhere except near the coast. In the case of the convection current, it is the actual heating rate, and this can be taken as zero everywhere except near the ground. The equation is non-linear since no linearizing assumptions are made in the analysis. Some results of the numerical integration, using the Deuce computer at the University of Glasgow, are shown in Figs. 3 and 4.

The initial development of the sea-breeze near the coast and its subsequent penetration inland are features of the result illustrated by Fig. 3, and the analogous generation of the convection current at the surface and its penetration upwards is illustrated in Fig. 4. In both cases the onset at a point away from the origin is fairly sudden and 'frontal' in nature. Another interesting feature is the series of pulses behind the initial one. There is observational evidence for this occurring after the onset of a sea-breeze, and Mr. Dixon's observations described earlier show this property for a convection current in water. These fluctuations may, however, have been introduced into the computation as a result of truncation errors in the finite-difference approximations used in the integration of the equation. Further computations with different heating-rates show that smaller currents develop more rapidly than larger ones, as one observes on a typical convection day when the larger clouds usually develop during the late morning or afternoon.

The symposium ended with a general discussion. Dr. Ludlam's dynamical picture of a thunderstorm was discussed at some length and it became obvious that here was a useful field of study for the dynamical meteorologist, for no mathematical theory which can account for even the broadest features of these storms at present exists.

R. P. PEARCE

SAFETY OF FACTORY WORKERS

THE annual report of the Chief Inspector of Factories for 1959 reports a further decline in the number of fatal accidents, from 665 in 1958 to 598 in 1959, the lowest figures recorded this century*. While this figure continues the consistent downward trend in fatalities from the 828 in 1951, the downward trend in total accidents of the previous three years was checked, and the number of reported accidents rose from 167,697 in 1958 to 174,071, in spite of increased activities in the field of accident prevention, although it may be partly explained by the increase in the number of people employed and hours worked. The Chief Inspector, however, finds the increase in the number of accidents to young

persons disturbing, and one of two chapters in the report dealing with subjects of interest without being necessarily restricted to the events of the year deals with the prevention of accidents to young persons. This has been discussed in *Nature* of November 5, p. 460; the other special chapter deals with designing machinery for safe operation. Besides directing attention to some of the more important safety principles, which, it is suggested, machine manufacturers should bear in mind, it urges that every opportunity should be taken to bring such considerations before the professional, research and teaching authorities concerned, and that industry as the user should insist on getting premises, plant and equipment with safety 'built in' by the suppliers.

As a result of a considerable number of changes made in the analysis and classification of information

* Ministry of Labour and National Service. Annual Report of the Chief Inspector of Factories for the year 1959. Pp. 128. (Cmd. 1107.) (London: H.M. Stationary Office.) 7s. net.

about reported accidents, it should be possible to make greater use of the information already provided in the accident reports, and in addition to tables analysing accidents by industry, causation and process, there is included for the first time a table giving accident incidence rates for most of the industries under the manufacturing headings of the Standard Industrial Classification, as revised in 1958. In a number of industries, research associations and other bodies have continued to examine important problems of health and safety, such as dust and fumes and dangerous machinery, and the Chief Inspector believes that other industries could, with advantage, make wider use of their research associations in helping to solve their own special problems in this field. During the year, thirteen inspectors were appointed to the general inspectorate and at the end of the year eight more were awaiting appointment. Twelve inspectors were recruited to the specialist branches, and at the end of the year 409 inspectors of all grades were in posts, but there were twenty-four

vacancies in the general inspectorate, one each in the Medical and the Electrical, and seven in the Chemical Branches.

At the end of 1959 there were 222,117 registered factories in Britain, compared with 223,085 in 1958, the decrease being almost entirely in the number of factories without mechanical power. An analysis in March showed that about one quarter of the factory population work in factories employing more than 1,000 people, but only four factories in every thousand are of this size, and on the other hand two-thirds of the number of factories employ fewer than ten people, but less than a thirtieth of the factory population. More than 26 per cent of reported accidents occurred in 'handling goods', 15.1 per cent were caused by falls of persons, and falls of all sorts accounted for 91 fatal accidents in factories, or 26 per cent of all fatalities. A chapter in the report reviewing the year mentions a number of industrial developments which have promoted greater safety in industry.

PHYTOGEOGRAPHY OF THE AUSTRALIAN REGION

DR. NANCY T. BURBIDGE has recently published a comprehensive account and analysis of the principal floristic regions of the vast Australian area, and of selected areas within it of special interest*; she has discussed the composition of the flora in relation to geological and geographical factors, and in a map of considerable interest she has indicated the probable paths of migration, chiefly by way of Sumatra, the Philippines and New Guinea, but including movements within the region, that have contributed to the contemporary phanerogamic vegetation. The phytogeographical region is regarded as including Australia and Tasmania, and can be divided into the tropical zone in the north and east, the temperate zone in the south and east, and the 'Eremsian' zone in the arid centre. While the demarcation of these zones is closely related to contemporary climatic conditions, the respective floras also show the results of selection by former climatic and geographical conditions.

Dr. Burbidge reports that although the flora of the South-West Province shows the highest proportion of endemism, there is a close relationship with the flora of the eastern part of the temperate zone. The Province, in fact, is not "the 'cradle' of the autochthonous elements of the Australian flora though it is apparently an asylum for many relict forms".

At the generic level the Tasmanian flora is not highly endemic, but it shows certain affinities with the flora of Malaysia and with genera found along the Malaysia-New Zealand arc or genera also occurring in South America. Some of the genera are unknown on the mainland, others are known from Australian Tertiary deposits. It appears that the Tasmanian flora includes relics from early Tertiary floras, survivors from the cold-climate regimes of the Pleistocene, and Australian elements which have

mingled with the flora during periods of land continuity.

The high rainfall habitats of north-east Queensland are remarkable for the large number of families, genera, and species which are restricted to them, that is, within the Australian region. Thus, many genera have only a single representative which may also occur in Malaysia. Dr. Burbidge considers that some of these may be recent arrivals while others, known as fossils from southern deposits, have a more restricted distribution than in the past. While the close affinity with the flora of New Guinea is noted, Dr. Burbidge points out that there are certain affinities with the floras of New Caledonia and New Zealand which may be independent of those of other parts of the Australian region.

The composition of the Australian flora is primarily attributable to climatic selection within the region and from the biotypes which have become available as a result of migration—migration by communities rather than by chance dispersal of individuals being regarded as a major factor.

The study of Tertiary floras, though not extensive, indicates an affinity with the flora of South America which is "contrasted with the marked lack of data suggesting a similarly increased relationship with southern Africa. The relationship between fossil and modern representatives of such genera as *Podocarpus*, *Dacrydium*, and *Nothofagus* suggests that there has been a northward migration or a withdrawal to warmer latitudes since the Tertiary. All the main elements of the present-day flora are represented in the Tertiary assemblages. If current views on the 'Malaysian' or 'tropical' nature of some affinities and the 'Antarctic' nature of others be accepted then there is no indication that the major migration into the Australian Region came from one particular direction".

* *Australian J. Bot.*, 8, 75 (1960).

Also comprised in the Australian flora are temperate species with northern hemisphere affinities. Some of these occur in temperate communities in both hemispheres, but others are endemic to, and characteristic of, the 'Eremsian' zone. It is thought that the flora of this zone may have originated from a coastal sand dune and littoral type; and it is suggested that it developed from elements that migrated to the Australian region as early as the Cretaceous when there may have been a coastal continuity with the Tethys Sea. A further suggestion is that these plants remained in coastal habitats but moved inland, possibly along southern estuarine coasts, and became isolated under arid conditions during the Pleistocene or Recent times.

From Dr. Burbidge's analysis, it appears that eastern Australia "has been a very important migration

route for a very long period, being linked with the northern hemisphere through Malaysia". The northward migration of Australian species has apparently been less successful than the southward migration of Malaysian ones, the ecological barrier afforded by dense tropical communities having inhibited the northward movement of the light-requiring Australian types: "The significance of such a barrier would be dependent on the climatic conditions during periods of land continuity between Australia and Malaysia and between Australia and New Guinea".

The view that Australia and New Zealand are constituent parts of a biogeographic region is regarded by Dr. Burbidge as unacceptable, unless such a region includes a portion of the island arc in the north-east.

THE WATER NET, *HYDRODICTYON*

THE water net, *Hydrodictyon reticulatum*, occurs only sporadically in Britain, but thanks to its ready growth in culture, the remarkable structure and unusual asexual reproduction of this rare alga have become familiar to many generations of students. Certain details of the life-history were hitherto obscure, however, and even less was known of other species of the genus. Our knowledge of the only three well-defined species, all occurring in South Africa, has now been greatly extended by the recent publication by Dr. M. A. Pocock (*J. South African Bot.*, 27, 187; 1960) of the results of detailed investigations which were in progress for a period of some twenty-five years. In addition to repeated examinations of materials collected in the field, extensive use was made of culture methods, the adoption of agar-plate cultures making it possible to follow the fate of individual cells and cœnocytes.

In all three species of *Hydrodictyon* the basic structure is a network of cœnocytes, each with many nuclei and conspicuous pyrenoids; but whereas in *H. reticulatum* (L.) Lagerheim the mature net is an elongated hollow cylinder, in the other two species (*H. africanum* Yamanouchi and *H. patenaeforme* Pocock) the cœnocytes form a flat typically one-layered plate. In *H. reticulatum* and *H. patenaeforme* the cœnocytes remain cylindrical, while in *H. africanum* they become spherical and dissociate, the individual cœnocytes developing independently for a considerable time.

In addition to these differences in the mature net, the three species differ in the details of their life-histories. It has long been known that in the asexual reproduction of *H. reticulatum* the protoplast of each cœnocyte divides into a large number of uninucleate zooids, which without being liberated rearrange themselves and unite to form a new net in the parent cœnocyte. There have been several differences of opinion as to certain details of this process, but the investigations of Dr. Pocock have clarified many points. In particular, it was found that at one stage in the process the zooids move freely among one another, all protoplasmic connexions between them having disappeared. Although the zooids are confined between the outer protoplasmic membrane and

the vacuolar membrane, forming a single peripheral layer, they do not adhere to either membrane. The vacuolar membrane persists throughout net formation, finally disappearing when the young net is liberated by the rupture of the outer wall. There is no asexual reproduction of this type in the other species of *Hydrodictyon*, where daughter nets are never produced within mature cœnocytes.

In *H. patenaeforme* and *H. africanum* the mature cœnocytes produce swimmers which are always liberated into the water. The swimmers of *H. patenaeforme* may either behave as gametes, fusing in pairs to form first a planozygote which finally becomes a hypnospore, or may act as asexual spores producing hypnospores without previous fusion. As in the earlier known sexual process of *H. reticulatum*, the gametes are isogamous. In *H. africanum* the gametes are anisogamous and there is still some doubt as to whether they can act as asexual spores. The asexual production of hypnospores is found only occasionally in *H. reticulatum*.

The hypnospores of all species, whether sexually produced (zygospores) or asexually (azygospores), may enter a prolonged resting phase or may germinate at once following a period of growth. In *H. reticulatum* and *H. patenaeforme* the hypnospores on germination produce comparatively large zoospores, one from azygospores, typically four or eight from zygospores. After a period of motility, each zoospore settles down and gives rise to a polyhedron stage. Following a period of growth the polyhedron in turn divides to form zooids, which unite to produce the germ net. In *H. africanum*, although polyhedra are occasionally formed, the zoospore and polyhedral stages are usually cut out of the life-cycle. In this species the germ net is produced directly on germination of the hypnospore.

From the details of the life-history and from what is known of the cytology of *H. reticulatum*, it seems clear that in all three species the net is haploid, with the zygospore as the only diploid phase in the life-history, reduction division occurring on germination of the zygospore. The polyhedron is an interpolated vegetative phase, peculiar to the family Hydrodictyaceae.

A. ALLSOPP

ROLE OF THE GRAIN COAT IN WHEAT GRAIN DEVELOPMENT

By A. H. G. C. RIJVEN and C. A. BANBURY

Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, Canberra

THE mature grain of wheat has a thin coat consisting of several layers of dead and obliterated cells, and these layers are singularly low in content of various enzymes^{1,2}. During the early development of the grain, however, such layers seem to be endowed with specific metabolic functions.

The first indication of this possibility arose from an attempt to correlate the ontogenetic pattern of glutamyl transferase content with the synthesis of gliadin in the developing wheat grain. A correlation was expected on the grounds that gliadin is particularly rich in glutamine³ and that glutamyl transferase is believed to be identical with glutamine synthetase⁴, and therefore responsible for glutamine synthesis. Moreover, it was considered possible that the transferase mediates the incorporation of glutamyl residues into the peptide chain of gliadin, which seems to contain *α*-glutamine⁵. However, when the determinations were carried out in 1958, with the variety *Insignia*, a rather different picture emerged (Fig. 1). The enzyme showed an early rise of activity, which began to fall 12 days after anthesis, that is, at a time when gliadin had scarcely begun to be produced. The peak of activity was not an artefact due to gradual accumulation of inhibitors or interfering enzymes. This was concluded from assays performed on deep-frozen material in which low activities of late harvests and high activities of early harvests appeared additive when the extracts were brought together.

In the 1959 season, closely similar observations were made on a different wheat variety, *Festival*, that is, a

peak of activity of glutamyl transferase was found at 12 days after anthesis.

At this stage of the work it was realized that the different parts of the developing grain show a complex histogenetic pattern. Nutman⁷ had directed attention to some of these phenomena and their possible physiological significance in rye. On macroscopic inspection, the most striking feature is the early growth of the grain coat, followed by its gradual decline and obliteration (Fig. 2); the endosperm shows a continuous growth in weight and volume. The peak in glutamyl transferase activity therefore seems to reflect changes in the coat rather than in the endosperm. This consideration led to investigations of the localization of the enzyme.

The complex composition and ontogeny of the outer layers of the wheat grain have been dealt with by Kudelka⁸ and Percival⁹. It comprises the pericarp, integuments and nucellus. Lacking any precise term, the term 'grain coat' has been adopted here for the whole structure. During the earlier stages of development this can be easily separated from the endosperm. Also, from about 8 days after anthesis, the outer pericarp can be separated from the rest of the grain coat.

Fig. 1 Wheat, variety *Insignia*. Time-course of glutamyl transferase activity, and of total- and gliadin-nitrogen content on a grain basis.

From the ears of a particular harvest day the first grain out of a spikelet from the centre of the ear was used. The grains were ground in a cold mortar and three times extracted with water. After centrifugation at 500*g*, the accumulated supernatants (1 grain per ml.) were used for the enzyme assay, in which the formation of glutamylhydroxamic acid is measured under conditions similar to Stumpf *et al.*⁴, the residue was extracted three times with 70 per cent ethanol, and gliadin was precipitated by adding 6 volumes of a mixture of 2 parts ethanol, 1 part ether and 0.01 per cent lithium chloride.

Fig. 2. Wheat, variety *Festival*. Right halves of abaxial and trans-sectional views of fixed grains harvested at 4-day intervals from anthesis. The blackened parts belong to the 'grain coat'; the gap (stippled) between outer pericarp and 'rest' of the grain coat, present from about 8 days after anthesis, is closed again at day 20. The endosperm (hatched) is at first only an acellular bag (see day 4).

Table 1. DISTRIBUTION OF SOME ENZYMES IN THE DEVELOPING GRAIN OF WHEAT

	Glutamyl transferase		Phosphatase		Leucine activating enzyme	
	$\Delta O.D.$ 540 $m\mu$	%	$\Delta O.D.$ 400 $m\mu$	%	$\Delta\%$ exchange	%
Outer pericarp	0.303	60	0.149	50	nil	nil
Rest of coat	0.201	40	0.092	31	2.17	29
Endosperm	0.002	nil	0.058	19	5.39	71

Deep-frozen wheat grains, variety Festival, harvested 16 days after anthesis. Observed enzymatic activities of extracts of different parts of the grain, and the corresponding percentages of the total activity of the whole grain.

Glutamyl transferase: change in optical density ($\Delta O.D.$) at 540 $m\mu$ (ref. 6) after incubation for 20 min. (30° C.) of extract equivalent of 0.5 grain.

Phosphatase: change in optical density at 400 $m\mu$ after incubation for 15 min. (30° C.) with disodium *p*-nitrophenol phosphate¹⁹ of extract equivalent of 0.5 grain.

Leucine-activating enzyme: change in per cent exchange between pyrophosphate and adenosine triphosphate¹³ after incubation for 15 min. (30° C.) of extract equivalent of 16 grains. Extracts were eluted phosphate gel purifications¹².

This 'rest' notably contains the chlorophyll layer, which is part of the pericarp. The outer pericarp of the earliest stages is opaque white, partly concealing the chlorophyll layer, but becomes more translucent as the grain starts to fill.

Glutamyl transferase activity was determined on extracts of outer pericarps, of 'rests' of grain coats and of isolated endosperms of deep-frozen 1959 material taken 16 days after anthesis. On a grain basis, 60 per cent of the activity appeared to be localized in the outer pericarp, 40 per cent in the rest of the grain coat and none was found in the endosperm. Neither was any activity found in isolated endosperms taken 32 days after anthesis. However, activity was found in concentrated extracts of endosperms, equivalent to 10 grains per ml., taken 12 days after anthesis. This amounted to 2 per cent of the activity of the grain coat. These results were confirmed using fresh material.

These observations suggest that the early peak in glutamyl transferase is associated with the early development of the grain coat and its gradual decline thereafter. They also suggest that the grain coat assumes a predominant role in the synthesis of the

glutamine which is synthesized inside the grain. Admittedly this constitutes probably only part, and perhaps even a minor part, of all the glutamine which is ever present in the grain from anthesis to maturity, because the main source is presumably elsewhere in the plant.

The observations of Table 1 provide further examples of the differential distribution of enzymes within the grain and indicate the probable importance of the grain coat in wheat grain development.

The distribution of phosphatase, at 16 days after anthesis, was: outer pericarp 50 per cent, rest of grain coat 31 per cent and endosperm 19 per cent. These figures may be compared with those on phytase of the mature grain², where the coat contributes 7 per cent.

Leucine-activating enzyme appeared to reside mainly in the endosperm (71 per cent), none was found in the outer pericarp, but there was considerable activity in extracts of the 'rest' of the grain coat (29 per cent). This contrast between the parts of the coat is probably due to the chlorophyll layer in the 'rest' of the coat. This is full of chloroplasts, and these have been shown to harbour amino-acid activating enzymes^{13,14}.

These investigations are being continued.

ANATOMICAL EVIDENCE FOR OLFACTORY FUNCTION IN SOME SPECIES OF BIRDS

By BETSY GARRETT BANG

Department of Pathobiology, Johns Hopkins University, Baltimore

THERE is good morphological evidence that inherent responses to chemical sensory stimuli are of vital importance to some birds. It seems curious that the large olfactory organs of certain species¹ have so often been pointed out by anatomists, yet most olfactory learning studies have been done on feebly equipped birds such as pigeons, and have tended to keep alive in the text-books the idea that the chemical sense in birds is minimal or lacking. The maze type and conditioned reflex studies on microsomatic forms and the succession of uncontrolled field-tests initiated by those of Audubon² have kept dust from settling on the question, but have proved nothing about birds with superior receptors. There has been one recent, controlled, statistically significant laboratory experiment on olfactory learning

in pigeons³, and even in these weakly endowed birds the results were positive.

In dissecting the nasal tissues of birds for work on natural defences against respiratory disease⁴, I have been repeatedly impressed by the size of some of the olfactory conchæ. Species were selected on the basis of the exposure of their nasal fossæ to extremes of environment, and not on the basis of olfactory behaviour. Of the species thus far dissected, by far the largest and most heavily innervated organs have been seen in the turkey vulture, *Cathartes aura*, the Trinidad oilbird, *Steatornis caripensis*, and the Laysan and black-footed albatrosses, *Diomedea immutabilis* and *D. nigripes*, each of which types represents a separate order with quite dissimilar feeding and nesting habits. Turkey vultures are diurnal carrion

feeders the solitary nests of which are found in sequestered hiding places; oilbirds feed nocturnally on fruits and nest colonially in total darkness in deep high caves in which they navigate by echo-location; the two pelagic albatross species feed mostly on marine crustaceans and nest colonially on islands, in the open, in shallow scrapes.

There is no question of degenerate or indifferent function of the olfactory organs of these birds. Other species seen in the course of this work have 1st nerve equipment varying from modest to considerable, but that of the three specified types is outstanding. In reviewing the literature on the habits of these particular birds, it is apparent that no definitive controlled experiments on the function or the sensitivity of the chemoreceptors have been done. It may be useful, however, to cite a few records of apparent olfactory behaviour in these species as clues to possible functions of the organs to be described.

Fig. 1

Turkey vultures are high-altitude hunters. They apparently detect food odours which rise on the thermal updraughts on which they glide. They have been seen to pass over carrion upon which they would have spiralled straight down to feast if vision was the stimulus; having overshoot the carrion until the scent was evidently carried up on the wind at an angle, they then turned suddenly and followed the scent beam to the prey⁵. A flock of 40-50 turkey vultures was seen to come in from a communal roost two miles away, sailing into the scent-laden trail of the first morning thermal to feed on offal which had been uncovered at dawn⁶. Fisher⁷ has reported that a turkey vulture will not feed on newly discovered carrion so long as a human observer is upwind of it, no matter how well concealed he thinks himself to be.

From the many eye-witness accounts of keen olfactory perception in albatrosses, Loye Miller's is selected because his observation cruise was planned and the birds were marked⁸. Black-footed albatrosses were marked during movements of an oceanographic vessel to six stations 30 miles apart, with a 2-hr. stop at each point. Bacon drippings poured on to the surface of the sea attracted marked birds from at least 20 miles away within an hour. The birds discriminated by olfaction between paint scum and bacon drippings, refusing to approach the paint flux but going directly to the drippings.

The function of the chemoreceptor in *Steatornis* has not yet been determined. Dr. D. W. Snow, who has been studying the oilbirds of Trinidad for several

Fig. 2

years, writes in a personal communication that olfaction may be important in food finding: "Where the olfactory sense may come in, I think, is in locating trees that are in fruit". Some of their food trees are highly aromatic, and ripe and unripe fruits are mixed in the bunch. These nocturnal birds have large blue light-sensitive eyes, and it is not known whether they can distinguish ripe fruits by vision. Oilbirds not only nest colonially but also communally with bats, in absolute darkness, like the oriental swiftlet *Collocalia*. Novick⁹ has recently suggested that the swiftlet may need a supplement to echo-location in discriminating its individual nest in a noisy crowded colony and that olfaction may serve this need. Many animals use musk secretions to mark territories, breeding sites, and family members for olfactory identification. Most species of bird secrete musk in their pygial glands, and these glands are known to be hyper-active in some species during nesting (hoopoes, wood-hoopoes, musk ducks, etc.). Turkey vulture nests smell of musk¹⁰, and the musk secreted by albatrosses and other petrels clings to nest sites and even to dried skins for years¹¹.

The three species illustrated in Figs. 1-3 each has nasal fossae precisely engineered to filter, warm, moisten, and sample inspired air chemically. Unfortunately, a sagittal view gives no concept of the airflow, nor does it demonstrate that the olfactory chamber is a cul-de-sac enclosed on three sides. The general arrangement of the structures in all the specimens is consistent with those of the oilbird

Fig. 3

(Fig. 2), though naturally the conchæ vary somewhat in relative size. The anterior concha, peculiar to birds, serves mostly as a baffle and thermo-regulator; the middle or respiratory one is covered with mucus-producing and ciliated cells; the posterior, olfactory, concha supports the free receptor fibrils of the 1st nerve and a quantity of serous glands peculiar to the olfactory organ. In each species the olfactory concha is conspicuously yellow in the fresh state. This concha is hollow in the albatrosses and the oilbird, the concavity being in communication with the cephalic air-sac system. The vulture concha is scrolled two and a half times, and has therefore a much greater surface area.

The mucosa of the conchæ was gently scraped away to reveal the underlying fibres of the olfactory nerve branches. As shown in Fig. 1, prominent branches are distributed over the entire convexity of the albatross concha. The network of end branches and fibrils was so thick in the turkey vulture that it was not possible to prepare a tidy dissection, and, as Fig. 3 shows, the entire surface was shaggy with torn nerves. The oilbird was photographed before the fibres were dissected out. The branches are somewhat closer together than those of the albatross but

not so crowded as those of the vulture. In each species, strong branches of the 1st nerve also lie along the roof, posterior and ventro-lateral walls, and upper portion of the septum nasi of the olfactory chamber.

Though experimental results are wanting, it is suggested therefore that on the combined evidence of morphology and field-observation, it is probable that birds possessing large olfactory organs may respond instinctively to chemical stimuli, either alone or in complex interaction with auditory, visual, vibratory, and other organs of special sense.

HYPOTHETICAL PATHWAY OF NITROGEN METABOLISM

By DR. GIOVANNI COSTA

Department of Medicine A, Roswell Park Memorial Institute, Buffalo, New York

THE concept is widely accepted that nitrogen which enters the body of mammals as food ultimately is either stored in the form of body protein or eliminated. Elimination occurs chiefly through urine and faeces, in the form of urea, ammonia, creatine, creatinine, uric acid, amino-acids and other known nitrogen-containing katabolites. This concept represents the rationale for the technique of nitrogen balance studies, in which the nitrogen, recovered from urine, faeces, hair, and cage wash, and measured according to one of the many available modifications of Kjeldahl's method, is subtracted from the intake.

It is implicit in such a concept that positive nitrogen balance values must, within the limitations represented by concomitant variations in the amounts of other body constituents, particularly water and fat, be paralleled by a proportional increase in body-weight. A factor of 30 has repeatedly been found adequate in converting nitrogen weight into 'live' weight of the animal, provided unusually large deposits of adipose tissue are not present¹.

In the present article, results are presented which are not immediately consistent with the accepted postulate. Large and long-term nitrogen 'retentions'

RELATIONSHIP BETWEEN NITROGEN INTAKE AND NITROGEN RETENTION IN TWO DOGS

have been seen in our animals without proportionate increase in body-weight. Analogous results have already appeared in the literature²⁻⁷ concerning several species, including man. My results, reached independently, confirm earlier observations and add

7	500	4.20	68	+0.70	14.5	15.1

new elements to this problem of impossibly high cumulative nitrogen 'retentions' without gain in weight. A hypothesis is advanced to explain the anomalous behaviour.

Dogs: Male mongrel dogs were kept in metabolic cages on a supplemented raw horse meat diet, and the nitrogen balance measured as described previously⁸. It was observed that animals, the body-weight of which remained practically constant throughout the experiment, were 'retaining' considerable amounts of nitrogen over long periods of time, as indicated in Table 1. The amount of nitrogen 'stored' by these animals is so large it could not have been retained at the expense of other body con-

in standard metabolic cages at a constant temperature of 78° F. Regular periods of light and darkness were pre-set by an automatic switch. The animals were fed diet A of Table 3 once daily. Feeding consisted of adding new food to the cage after transferring the amount left over from the previous feeding to a separate compartment of the feeder. Animals were thus exposed to food at all times. Urines were preserved by addition of 50 ml. of 1 N sulphuric acid to the container placed under the funnel-shaped bottom of the cage. Urines and faeces were collected three times a week and analysed separately. Hair and whatever nitrogen could be recovered from the cages by careful washing with distilled water were collected together with stools. Nitrogen determinations were performed as described previously⁸.

Rats were distributed among three groups, receiving different amounts of nitrogen. The results are presented in Table 4.

With the cages used in this experiment, separation of stools from urine was accomplished by means of a fine-mesh screen placed between the animal and the flask where urine was collected. It was thus possible that some urine might have been absorbed by the stools. Some urea could have been converted to ammonia gas and thus have escaped collection. To obviate this possibility, and to reduce experimental errors further, another experiment with rats was carried out.

Experiment 2: Special metabolic cages were constructed. They consisted of a 'Pyrex' animal jar divided, by means of a coarse (No. 3 mesh) stainless steel screen, into an upper compartment housing the animal and a lower compartment containing 450 ml. of 1 N sulphuric acid. Urine, faeces and other solid and liquid matter were thus immediately collected in the lower compartment under sulphuric acid. Food was offered in a special feeder, consisting of an outer stainless steel cup covered with a screen in which was set a smaller 'Pyrex' beaker. This permitted the food spilled by the animal to be safely collected on the bottom of the outer cup.

New food was offered once a day as described for Experiment 1. Cages, feeders and screens were copiously washed and urine, faeces, spilled food, food

Table 3. COMPOSITION OF THE DIETS USED IN THE RAT AND MOUSE EXPERIMENTS

stituents. To explore this phenomenon further, the effect of varied nitrogen intakes was studied. Two dogs were observed, and the results are summarized in Table 2 and Fig. 1. Reasonable nitrogen equilibrium was obtained over a limited range of nitrogen intakes (periods 4-7). Above that range, a direct relationship existed between intake and 'retention'. No concomitant increase in body-weight was observed even when more than 4 gm. of nitrogen was 'retained' daily for 36 consecutive days.

Rats: Experiment 1: Adult male Sprague-Dawley rats, weighing between 460 and 510 gm., were kept

* Nitrogen retained $\times$ 30.

left over and whatever could be collected by repeated washings, were pooled and analysed in a single weekly pool. Food left over was weighed before it was added to the 'cage content pool'. At the end of the washing, the cages appeared absolutely clean and no traces of solid matter could be seen.

Although this method gives no information concerning the partition of nitrogen between urine, faeces and other potential routes of elimination such as hair, nails, or saliva, it has the advantage of yielding the most accurate results concerning the nitrogen balance, because it eliminates multiple errors possible in the determination of several components rather than a single pool. Before analysis, the 'pool' was homogenized for 5 min. in a large blender and brought to volume with enough sulphuric acid to make the final concentration 30 per cent (v/v). Food was analysed in lots equal to the weekly offering, following a procedure identical to that used for the 'pool'.

In Table 5, the relationship between nitrogen intake, nitrogen 'retention' and changes in body-weight is shown for various diets and various nitrogen intakes. The results obtained with the less-critical method of collection (Table 4) are substantially confirmed. Unfortunately, the variations in body-weight are not as demonstrative as those presented in Table 4. It is clearly evident, nevertheless, that they are independent of the nitrogen retention, and most likely represent fat storage.

Mice: Experiments with mice were carried out exactly as in rat experiment 2 except for smaller metabolic cages.

In Table 6, the nitrogen balances and variations in body-weight are presented at two different levels of nitrogen intake. It is interesting to note the higher fraction of the intake 'retained' by mice as compared with rats.

Over long periods of time, our animals have 'retained' large quantities of nitrogen. In some experiments, these were in excess of the amount the whole animal could have contained at the beginning of the experiment. Nevertheless, this nitrogen 'retention' was not represented by gain in weight.

The 'retention' observed does not appear to be due to a technical artefact. This point is supported by the following considerations: The validity of the Kjeldahl method used was tested by analysing compounds the composition and purity of which were verified by independent carbon and hydrogen analysis. Twenty-five commonly occurring amino-acids and

representative naturally occurring purines were analysed and gave results within 1 per cent of the theoretical value. Experiments were designed which maintained nitrogen equilibrium in dogs at suitably low nitrogen intakes, thus confirming the accuracy and completeness of our collections.

The length and magnitude of the 'retention' makes untenable the explanation that nitrogen could be stored at the expense of other constituents of the body. It should be added that, whenever tested^{6,7}, experimental evidence has not supported such an interpretation.

The hypothesis that some of the nitrogen fed in excess is eliminated through an unmeasured and hitherto unrecognized pathway would explain the discrepancies noted in a simple and rational way.

It does not seem likely that such a pathway could be represented by colonic flatus. Data available in man^{8,9,10} show that such a pathway is possibly quantitatively insufficient as a route for loss of nitrogen. The small amounts of ammonia eliminated via respiration^{14,15} would also fail to represent a quantitatively satisfactory explanation of our results.

The 'retention' occurs to a significant extent only when excess nitrogen is offered to the animal, as though such a pathway were active in providing a clearing mechanism for the nitrogen not warranted by metabolic need of the organism. This characteristic suggests the following schema:

That X is eliminated through respiration appears a likely possibility. If X exists and is represented by nitrogen gas, an amount which could explain the discrepancy between gain in body-weight and 'retention' would go undetected by the usual methods of analysis of nitrogen gas, being less than one-thousandth of the nitrogen involved in the respiration during 24 hr.

The non-participation of nitrogen in respiratory exchange has been postulated rather than proved. On the contrary, the few results available^{12,15} suggest that nitrogen does participate in the respiratory exchange. The possibility that other gases in

* Nitrogen retention $\times$ 30.

addition to nitrogen and ammonia and involving nitrogen could be eliminated via respiration has not been excluded.

The presence of a metabolic route of food nitrogen different from those already known could offer an explanation for the so-called specific dynamic action of protein. It should be remembered that the specific dynamic action is shown when 'excess' protein is fed to an animal in weight-equilibrium, but is absent when the same protein, although possibly fed in 'excess', is stored in the growing organism. My schema is consistent with such findings, and could explain the production of the 'extra' heat with the production of X through a chain of metabolic steps which might well be exothermic. The fact that specific dynamic action does not occur after hepatectomy and that only a few amino-acids are capable of eliciting it under particular experimental conditions^{16,17} is not inconsistent with my hypothesis.

Several anomalies of mammalian nitrogen metabolism could be explained in a simple and credible way by the loss in appreciable amounts of a nitrogen-containing metabolite, eliminated possibly through respiration. Adequate respirometers have been constructed, and an investigation involving the use of

nitrogen-15 is under way in our laboratory, at the pre-clinical and clinical level, to confirm or disprove this hypothesis, with the ultimate aim of identification of the pathway and its metabolites.

This investigation was supported in part by grant P-216 from the American Cancer Society.

ENERGETIC ASPECTS OF THE MITOCHONDRIAL OXIDATION OF SUCCINATE

By DR. GIOVANNI FELICE AZZONE* and DR. LARS ERNSTER

Wenner-Gren Institute, University of Stockholm, Sweden

AND

DR. MARTIN KLINGENBERG

Institute of Physiological Chemistry, Marburg/Lahn, Germany

THE reaction mechanism by which the enzymic oxidation of succinate is linked to the terminal electron transport system of intact mitochondria has been the subject of intense work during the past decade. Recent work in both the present laboratories, as well as in Chance's laboratory, has directed attention towards some new energetic aspects of this mechanism.

Prompted by an early observation of Chance and Hollunger¹, Klingenberg *et al.*^{2,3}, demonstrated that the addition of succinate to mitochondria, which were in a state of respiratory control ("State 4" in Chance's terminology), was followed by a considerable reduction of the intramitochondrial pyridine nucleotide. The extent of this reduction was higher than than obtained with pyridine nucleotide-linked substrates. It was postulated that this succinate-linked reduction of the mitochondrial pyridine nucleotide is an energy-requiring process, which, as recently reported by Chance and Hollunger⁴, is inhibited by uncouplers of oxidative phosphorylation, and is not restored in this state by added adenosine triphosphate. It has also been shown that a similar high extent of reduction of the mitochondrial pyridine nucleotide may be obtained by another flavin-linked substrate, glycerol-1-phosphate^{5,6}, and that both the succinate-

and the glycerol-1-phosphate-induced reduction may, in some instances, require the presence of added adenosine triphosphate⁶. In these instances also the reduction of a flavoprotein was found to be dependent on oxidative phosphorylation⁶.

Recently it was reported by Azzone and Ernster⁷, that the aerobic oxidation of succinate is greatly inhibited in rat liver mitochondria which had been depleted of endogenous high-energy phosphate by incubation, under appropriate conditions, with arsenate and/or agents which uncouple oxidative phosphorylation. In these mitochondria the rate of aerobic oxidation of succinate could be greatly stimulated by the addition of adenosine triphosphate, and this effect was not abolished by the simultaneous presence of uncouplers of phosphorylation. It was postulated that, under these conditions, the aerobic oxidation of succinate requires high-energy phosphate and that this energy can be supplied by added adenosine triphosphate through a reaction mechanism which is not inhibited by uncouplers of electron transport-coupled phosphorylation.

The objective of the present work was to elucidate the possible relation between the energy requirement of succinate oxidation and the energy-requiring reduction of pyridine nucleotide. In particular, it was of interest to investigate whether the adenosine triphosphate-induced stimulation of the aerobic

Fig. 1. Simultaneous recording of respiration (a) and pyridine nucleotide absorption (b). Bat liver mitochondria, 3.8 mgm. prot./ml. in 0.13 M potassium chloride, 0.008 M Magnesium chloride, 0.02 M triethanolamine hydrochloride, pH 7.5. As, arsenate; Dic, dicoumarol; Succ, succinate. Discontinuous absorption trace at the addition of dicoumarol because of compensation for the dicoumarol absorption. The numbers indicate the moments of extraction for pyridine nucleotide analysis, the results of which are given in Table 1.

oxidation of succinate in mitochondria depleted of high-energy phosphate is accompanied by a reduction of the mitochondrial pyridine nucleotide, and whether this process, similarly to the adenosine triphosphate-induced respiratory stimulation, can take place in the presence of uncouplers. The results presented here clearly indicate that this is the case. Qualitative and quantitative estimates of the reduced pyridine nucleotides were also carried out, and, in addition, data were obtained on the oxido-reduction states of the mitochondrial flavin and cytochrome *b*. Some implications of these findings for the mechanism of the functional link of succinic dehydrogenase to the terminal electron transport system will be considered.

The experiments entailed a simultaneous measurement of the oxygen uptake and of the difference in spectral absorption at suitable wave-lengths, using a double-beam spectrophotometer equipped with a vibrating oxygen electrode⁸. Twice-washed rat liver mitochondria were prepared as previously described by Klingenberg *et al.*². The incubation medium contained 0.13 M potassium chloride, 0.02 M triethanolamine buffer, pH 7.5, and 0.008 M magnesium chloride. The measurements were carried out at 25°C. in quartz cuvettes of 0.5 and 1 cm. light-path. Extractions and enzymic determinations of the reduced and oxidized pyridine nucleotides were performed essentially as described previously².

A typical experiment is shown in Fig. 1. In this experiment, the mitochondria were pre-incubated for 3 min. in the presence of arsenate and dicoumarol. The endogenous respiration was rather high at the onset of the pre-incubation, but declined to almost zero after about 2 min. Subsequent addition of

succinate resulted in a relatively low respiration, which, however, could be greatly stimulated by the addition of adenosine triphosphate in accordance with previous findings⁷. As seen in the lower curve of Fig. 1, the 340-380 m μ absorption difference, indicative of the reduction state of the pyridine nucleotides, decreased rapidly during the initial period of the pre-incubation. This decrease levelled off concomitantly with the decline of the endogenous respiration. The addition of succinate induced no change in the steady state of the pyridine nucleotide, whereas the subsequent addition of adenosine triphosphate caused a reduction of the pyridine nucleotide. A new steady-state level was reached after about 1 min. It may be noticed that both the stimulation of the respiration and the increase of the 340-380 m μ absorption required a short lag-period, following the addition of adenosine triphosphate.

To ascertain if the spectrophotometric changes were relevant to the reduction of pyridine nucleotide, enzymic determinations were performed. For this purpose, a parallel experiment was carried out with a 10-ml. sample of the incubation mixture, from which successive aliquots were removed and extracted at the moments indicated in Fig. 1. The results of the di- and tri-phosphopyridine nucleotide determinations are given in Table 1 (a). The total levels of reduced pyridine nucleotide found in the various aliquots were in agreement with the spectrophotometric data. A decrease was found of the total reduced pyridine nucleotide during the pre-incubation, followed by no change on the addition of succinate, and by an increase on the addition of adenosine triphosphate.

It may also be seen in Table 1 that the adenosine triphosphate-induced reduction of the pyridine nucleotide was accounted for mainly by an increase of reduced triphosphopyridine nucleotide, and only to a small extent by an increase of reduced diphosphopyridine nucleotide. These results, which are in agreement with previous findings^{2,3}, indicate that in the mitochondria there occurs a transfer of hydrogen between reduced di- and tri-phosphopyridine nucleotide by way of a mechanism which favours the accumulation of the latter compound. The fact that the mitochondrial pyridine nucleotide transhydrogenase⁹ cannot account for the presence of a higher level of reduced triphosphopyridine nucleotide suggests that other transhydrogenase mechanisms¹⁰ may also be involved.

The total levels of both reduced pyridine nucleotides, attained upon the addition of adenosine

triphosphate, were relatively low in these experiments (5–10 per cent for diphosphopyridine nucleotides and about 30 per cent for triphosphopyridine nucleotides) as compared with those previously observed^{1,3} in mitochondria under respiratory control in the presence of succinate (75 and 95 per cent, respectively). However, the present levels are in fair agreement with those found^{1,3} when an uncoupler of oxidative phosphorylation was added to this latter system, subsequent to the addition of succinate. These levels would therefore seem to represent the maxima obtainable in a state of uncontrolled respiration.

In Table 2, data are summarized which show the influence of various pre-incubating conditions on the phenomenon described above. Replacement of dicoumarol by dinitrophenol had no major effect on the respiratory rate either before or after the addition of adenosine triphosphate. On the other hand, the extent of reduction of the mitochondrial pyridine nucleotide following the addition of adenosine triphosphate was lowered to about one-half.

Table 2. EFFECT OF ADENOSINE TRIPHOSPHATE ON SUCCINATE RESPIRATION AND PYRIDINE NUCLEOTIDE REDUCTION OF PRE-INCUBATED LIVER MITOCHONDRIA

Pre-incubation with	Oxygen uptake with 4 mM succinate before after addition of 2 mM ATP		Absorbancy increase E' at 340–380 mμ (cf. Fig. 1b) on addition of 2 mM ATP
	μ atom O min. gm. prot.		$\frac{1}{\text{cm. gm. prot.}}$
2 mM arsenate + 0.04 mM dicoumarol	13	55	11
2 mM arsenate + 0.1 mM DNP	12	44	5.5
0.1 mM DNP	20	43	5
2 mM arsenate	40	no ATP added (succinate alone)	30

Pre-incubation with arsenate alone resulted in a low rate of respiration with succinate, which, however, gradually increased even without the addition of adenosine triphosphate. As suggested elsewhere¹¹, this effect may be attributed to a resynthesis of high-energy phosphate within the mitochondria during the course of succinate oxidation. The gradual increase of the respiratory rate was paralleled by a reduction of the pyridine nucleotide, which reached a steady-state level of about twice that attained in the presence of adenosine triphosphate in the arsenate-dicoumarol-pretreated system.

When the mitochondria were pre-incubated with dinitrophenol (or dicoumarol) in the absence of arsenate, an inhibition of the subsequent respiration with succinate was also obtained, although the inhibition was weaker than in the simultaneous presence of arsenate. The rate of the inhibited respiration, however, was constant, exhibiting no tendency to increase without the addition of adenosine triphosphate as in the case of pre-treatment with arsenate alone. Adenosine triphosphate gave a stimulation of the respiration in this case also, and again, this effect was accompanied by a reduction of the pyridine nucleotide. The steady-state level reached in the presence of dinitrophenol alone was about the same as in the simultaneous presence of arsenate. Enzymic determinations on the reduced pyridine nucleotide levels in the dinitrophenol system are shown in Table 1 (b).

Fig. 2. Recording of flavin and cytochrome *b* absorption (cf. legend of Fig. 1). The mitochondria had been pre-treated, as indicated, for 3 min. until succinate addition.

The difference in findings with dinitrophenol alone and arsenate alone as pre-incubating agents may be ascribed to the fact that although arsenate is very efficient in depleting mitochondria of high-energy phosphate it is a weak uncoupler of electron transport-coupled phosphorylation, whereas dinitrophenol is a potent uncoupler, but rather poor in depleting the mitochondria of high-energy phosphate. As shown elsewhere¹¹, dinitrophenol can efficiently deplete mitochondria of high-energy phosphate in the presence of adenosine-5'-phosphate.

Under all the conditions tested in Table 2, the rate of reduction of the pyridine nucleotide was approximately the same.

In other experiments, the changes in oxidation-reduction states of the mitochondrial flavin and cytochrome *b* were followed (Fig. 2). Increased levels of reduction of both these components were recorded following the stimulation of succinate oxidation by the addition of adenosine triphosphate in mitochondria that were depleted of high-energy phosphate.

A difference in the extent and rate of the adenosine triphosphate-induced reduction of the flavin was observed according to whether dinitrophenol or dicoumarol was used as a pre-incubating agent in combination with arsenate. In the case of dicoumarol, the change in the steady state of the flavin was diphasic and the amount of flavin reduced was about twice that obtained with dinitrophenol. As was observed above (Table 2), the reduced pyridine nucleotide level was also about twice or higher in the dicoumarol system than that attained with the dinitrophenol system. These findings may be related to the observation previously reported that dicoumarol, besides its uncoupling effect, is a powerful inhibitor of a soluble, pyridine nucleotide-unspecific diaphorase which is also found in mitochondria¹². In support of this concept, addition of both dinitrophenol and dicoumarol to the present system resulted in an adenosine triphosphate-induced reduction of flavin of the same rate and extent as that obtained in the presence of dicoumarol alone.

The possibility that oxaloacetate was responsible for the observed inhibition of succinate oxidation after the arsenate-dicoumarol incubation was previously⁷ discarded on the evidence that cysteine sulphonic acid, which removes oxaloacetate by trans-

amination to aspartate, could not restore succinate oxidation. This question was re-investigated in the present work by measuring directly the oxaloacetate concentration after the arsenate-dicoumarol pre-incubation. In no case was it possible to find oxaloacetate in the incubation mixture in amounts exceeding the sensitivity of the method used; that is, $5 \times 10^{-8} M$. Furthermore, since it has been demonstrated that adenosine triphosphate can remove the oxaloacetic inhibition by formation of phosphoenolpyruvate¹³, this compound also was determined. The concentration of phosphoenolpyruvate was ascertained to be less than $5 \times 10^{-7} M$ and thus cannot account for the observed adenosine triphosphate effect.

The present findings are at some variance with those recently reported by Chance and Hollunger⁴. These authors found no increase in the reduction of pyridine nucleotides following the addition of adenosine triphosphate in the presence of even very low concentrations of uncouplers. In the present case, added adenosine triphosphate clearly was able to induce a reduction of the pyridine nucleotide in the presence of concentrations of dinitrophenol or dicoumarol, which fully uncouple oxidative phosphorylation. It would seem, however, that, although the experiments of Chance and Hollunger, and those in the present work, were made with mitochondria of very different initial functional states, the discrepancy in the findings may not be due to different reaction mechanisms, but rather to a possible difference in the suitability of the two sets of conditions for allowing this adenosine triphosphate effect to become manifest.

The results presented here indicate a striking parallelism between the effect of adenosine triphosphate on respiration and on pyridine nucleotide reduction, and therefore suggest that under the present conditions the energy requirement for the two processes is utilized through a common intermediate. It would also seem that the common high-energy intermediate, which is formed during the oxidation of succinate, and the energy of which may be utilized for pyridine nucleotide reduction, is situated in the initial part of the respiratory chain, thus being probably closely related to the primary high-energy intermediate involved in the first respiratory chain phosphorylation. Furthermore, since the need for energy to initiate succinate oxidation is thought to be a normal property of intact mitochondria, it follows from the above reasoning that the site of entrance of electrons from succinic dehydrogenase to the mitochondrial respiratory chain should be prior to the level of cytochrome *b*; otherwise, the aerobic oxidation of succinate could not result normally in a phosphate/oxygen ratio of 2.

From the fact that concentrations of dinitrophenol which uncouple oxidative phosphorylation do not abolish the stimulatory effects of adenosine triphosphate on succinate-oxidation and on reduction of pyridine nucleotide by succinate, it appears that energy of adenosine triphosphate is available to the respiratory chain in spite of the presence of uncouplers of oxidative phosphorylation. This observation seems scarcely compatible with those hypotheses of oxidative phosphorylation¹⁴ in which a non-phosphorylated high-energy intermediate, susceptible to hydrolysis in the presence of dinitrophenol, is involved between adenosine triphosphate and

the respiratory chain. On the other hand, these results are consistent with those hypotheses which postulate the formation of a high-energy phosphate compound involving a respiratory carrier such as flavin¹⁵, or a quinone¹⁶, as primary intermediate of electron transport coupled phosphorylation. As has been pointed out previously¹⁵, in this type of hypothesis dinitrophenol is supposed to act by interfering with the activation of inorganic orthophosphate, thus inhibiting only the forward, but not the backward, reaction of respiratory chain phosphorylations.

Fig. 3. Hypothetical scheme of the functional link of succinic dehydrogenase to the terminal electron transport system. Symbols: DPN, diphosphopyridine nucleotide; TPN, triphosphopyridine nucleotide; *FpD*, DPN diaphorase; *FpS*, succinic dehydrogenase; *Pi*, inorganic phosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate.

Fig. 3 shows a tentative scheme covering these conclusions. It is suggested that the electrons from reduced succinic dehydrogenase enter the respiratory chain at the level of the diaphorase flavin, or alternatively, at the level of a quinone situated between the diaphorase flavin and cytochrome *b*. In order to react with these carriers the reduced succinic dehydrogenase requires the intervention of high-energy phosphate, with the reduced phosphorylated diaphorase or quinone as the reaction product. This product can react either with cytochrome *b*, resulting in the regeneration of adenosine triphosphate, or with diphosphopyridine nucleotide, with the liberation of orthophosphate.

Reaction of the artificial antigens and haptens with horse anti E. coli sera. Precipitation of *E. coli* O111 polysaccharide of a horse anti *E. coli* O 111 serum was inhibited by various preparations in the following order: α -aminophenyl-colito-pyranoside $>$ β -amino-

Fig. 1. Per cent precipitation of horse anti *E. coli* O 111 and anti *E. coli* O 55 antibodies by artificial colitose antigens. O 111 = Polysaccharide extracted from *E. coli* O 111; O 55 = polysaccharide extracted from *E. coli* O 55; α - and β -Co-Bo = α - and β -colitose phenylazo-bovalbumin

phenyl-colito-pyranoside > colitose. In the *E. coli* O 111 antigen the immunologically determinant colitose end-groups must therefore be linked as colito-pyranoside. It is not known at present whether or not the relatively strong inhibition of the β -isomer, as compared to colitose, is due to contamination with small amounts of the α -isomer.

The four colitose phenylazo-proteins gave strong precipitation with a horse anti *E. coli* O 111 serum and a weaker precipitation with a horse anti *E. coli* O 55 serum. Absorption of each of the antisera with the respective homologous polysaccharide markedly diminished the precipitating antibodies towards the artificial antigens. Moreover, after absorption of the antisera with the heterologous cross-reacting polysaccharide, precipitation of the anti *E. coli* O 111 serum with the artificial colitose antigens was only slightly diminished, whereas precipitation of the anti *E. coli* O 55 serum with the artificial antigens was completely abolished, as shown in Fig. 1. This suggests that in horse anti O 55 serum the small proportion of antibodies which reacts with the artificial colitose antigens is only contained in the antibodies cross-reacting with *E. coli* O 111 polysaccharide. In these experiments no difference in serological behaviour was found between the α - and β -colitosides.

Immunization of animals with artificial colitose-antigens. Rabbits were injected with each of the colitose-phenylazo-proteins. In nine out of thirteen sera precipitins against the artificial α - or β -colitose antigens were developed during immunization. Some of the precipitations were very strong. Inhibition by

colitose and aminophenyl-colitosides indicated that these precipitations were due mostly, if not completely, to anti-colitose antibodies. Bacterial colitose-containing polysaccharides were not precipitated by anti-colitose rabbit sera. Two sera agglutinated *E. coli* O 111 suspensions as well as erythrocytes sensitized with the corresponding lipopolysaccharide^{14,15}. However, the titres were relatively low, and no correlation was found with the levels of anti-colitose antibodies.

One goat (goat 1) was immunized with α -Co-Bo and a second goat (goat 2) with β -Co-Bo. The antisera obtained gave precipitin reactions with colitose-ovalbumin antigens (α -Co-Ov and β -Co-Ov), showing that specific anti-colitose antibodies had been formed. In addition, the sera were found to contain antibodies which specifically cross-reacted with *E. coli* O 111, that is, they precipitated *E. coli* O 111 polysaccharide; erythrocytes sensitized with *E. coli* O 111 lipopolysaccharide and suspensions of heated *E. coli* O 111 organisms were agglutinated, as shown in Table 1. On the other hand, the sera did not react with *E. coli* O 55 polysaccharide (no precipitation, no haemagglutination), but one of the two sera agglutinated suspensions of *E. coli* O 55 organisms (goat 1). This antiserum behaved exactly like an anti *E. coli* O 111 horse or goat serum. *E. coli* O 111 polysaccharide removed all agglutinating antibodies from this serum. Furthermore, in haemagglutination tests the two sera cross-reacted with all bacterial species serologically related to *E. coli* O 111 (*Salmonella* O 35, *Arizona* O 20), but not with species serologically related to *E. coli* O 55 (*Salmonella* O 50, *Arizona* O 9). The goat sera before immunization showed low titres of natural antibodies against practically all tested enterobacterial O antigens. After immunization with the artificial colitose-antigens only, titres against *E. coli* O 111 and serologically related strains were found to be markedly elevated (Table 1).

Twenty years ago W. F. Goebel^{16,17} described the isolation of cellobiuronic acid as the determinant group of the capsular polysaccharide antigen of *Pneumococcus* type III and the synthesis of an artificial antigen by coupling diazotized *p*-aminobenzyl cellobiuronide to protein. The antisera so obtained strongly precipitated type III polysaccharide and agglutinated type III *Pneumococci*. Furthermore, they protected animals against otherwise fatal infections with virulent cultures of these Gram-

* Haemagglutination of erythrocytes sensitized with lipopolysaccharides (see ref. 14). † Agglutination of heated suspensions

All strains (a) contain colitose and cross-react. All strains (b) contain colitose and cross-react but not with strains (a). All strains (c) do not contain colitose and do not cross-react either between them or with strains (a) and (b).

positive organisms. The present article reports the first artificial antigen which stimulates antibodies against certain pathogenic Gram-negative bacteria.

In agreement with previous inhibition work⁶, experiments described here show that a single monosaccharide unit—colitose—suffices to account to a high degree for the antigenic specificity of *E. coli* O 111 and serologically related bacteria (*Salmonella* O 35, *Arizona* O 20).

Rabbit antisera prepared against artificial colitose antigens were frequently found to be rich in specific anticolitose antibodies; they reacted only weakly, if at all, with the microbial colitose-containing polysaccharides. On the other hand, the two goat sera reacted strongly with the microbial polysaccharides although they showed lower titres of precipitating anticolitose antibodies, as compared with the rabbit sera. The quality of the antibodies obtained from the two species is obviously very different. This is a further example of the significance of the species in immunization with respect to the specificity of antibodies obtained by one and the same antigen.

Only one group of bacterial polysaccharides containing terminal colitose (*E. coli* O 111, *Salmonella* O 35, *Arizona* O 20) cross-reacted with goat antisera to the artificial colitose antigens, in perfect agreement with the finding that only anti *E. coli* O 111 antibodies precipitate colitose phenylazo-proteins. In the polysaccharide antigens of the *E. coli* O 111 group the structural arrangement of the terminally linked colitose appears to be similar to that of colitose in the artificial colitose antigens. On the other hand, on the basis of the findings reported here, the status of the likewise terminally bound colitose in the polysaccharides of the *E. coli* O 55 group (*E. coli* O 55, *Salmon-*

ella O 50, *Arizona* O 9) has again been shown to be different^{7,10}.

It should be pointed out that, in contrast to the bacterial endotoxic O antigen complexes, the artificial colitose antigens are practically non-toxic.

Work on the biological properties of anticolitose goat sera is in progress. Anticolitose sera from other animal species will be examined. The preparation of other 3,6-dideoxy-hexose phenylazo-proteins and investigations of their immunological properties are also under way.

Experimental details will be given elsewhere.

We are grateful to Prof. F. Kauffmann, Statens Serum Institut, Copenhagen, for discussing the manuscript and for confirming the haem agglutination experiments with a goat anti-colitose serum.

OCCURRENCE OF D-PHENYLALANINE, D-ALLOTHREONINE AND OTHER D-AMINO-ACIDS IN PEPTIDO-LIPIDS OF BACTERIAL ORIGIN

By DR. MIYOSHI IKAWA and DR. ESMOND E. SNELL
Department of Biochemistry, University of California, Berkeley, California

AND

DR. EDGAR LEDERER
Institut de Biologie Physico-Chimique, Paris

WORK on the chemical constitution of antibiotics has shown that a large number of these substances contain amino-acids of the D-configuration^{1,2}. The occurrence of D-amino-acids in functional structures of living cells has been reported much more rarely. However, D-alanine, D-glutamic acid, and D-aspartic acid have been shown recently to be common and major constituents of the bacterial cell wall³⁻⁷, and D-alanine and D-glutamic acid have been found to be present in the 'spore peptide' of *Bacillus megaterium*⁸. Moreover, α,ϵ -diaminopimelic acid, a major constituent of many bacterial cell walls⁹, possesses the *meso*-configuration for a large number of micro-organisms¹⁰. Certain nucleotides exemplified by those that accumulate in penicillin-treated *Staphylococcus aureus*¹¹, and which afterwards have been implicated as probable precursors in the biosynthesis of cell walls¹² also contain D-amino-acids. In all the above instances the D-amino-acids occur in products of microbiological origin. The occurrence of these compounds in higher plants and animals seems, from reports to date, to be a rarer event.

Recently, however, D-serine has been found in lombricine isolated from the earthworm, *Lumbricus terrestris*¹³.

We wish to describe here the general occurrence of several different D-amino acids in peptido-lipids and peptido-glyco-lipids from bacteria of the order Actinomycetales¹⁴.

The general approach has been to separate individual amino-acids by column chromatography, and then to compare the analytical values obtained through application of the ninhydrin method with those obtained by optically specific microbiological assay methods. Major discrepancies between the two methods of analysis have proved very useful in pointing out the presence of 'unnatural' forms of certain of the amino-acids, the presence of which was then confirmed by other methods. The substances included in this work are described briefly below.

(1) 'Wax D' of *Mycobacterium tuberculosis* var. *hominis* (Brévannes). The purification and composition of this material has been previously described¹⁵. The amino-acid components were reported

(a) Colorimetric ninhydrin method (ref. 21).

(b) Microbiological assay with *Leuconostoc citrovorum* (ref. 22).(c) D-Amino-acid oxidase assay. An active enzyme preparation was obtained by extraction of acetone-dried sheep kidney powder with 0.017 M pH 8.3 pyrophosphate buffer (ref. 23) followed by high-speed centrifugation. To the test sample in 1.3 ml. volume in water were added 1 ml. of 0.1 M pH 8.3 pyrophosphate buffer and 0.2 ml. enzyme and the mixture incubated at 37° with shaking for 1 hr. One ml. of 0.1 per cent 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid was then added, the mixture allowed to stand at room temperature for 15 min., 5 ml. of 2.6 N sodium hydroxide added, and the optical density at 520 m μ read after 10 min. (ref. 24). The appropriate D-amino-acid was used as the standard. Control experiments showed no oxidation of the L-amino-acids.(d) Microbiological assay with *Leuconostoc mesenteroides* (ref. 25).(e) Microbiological assay as described in ref. 25, but using *Lactobacillus pentosus* 124-2 as test organism. Turbidities were read after 48-72 hr. of incubation.(f) Microbiological assay (ref. 25) but using *Streptococcus faecalis* R as test organism.

(g) Direct neutralization of the ammonia fraction from the 'Dowex-50' columns with modified Nessler's reagent (ref. 26).

(h) Glycine (6 μ moles) and the following amino-acids of undetermined configurations were also detected; serine-threonine, 41 μ moles; valine, 8 μ moles; leucine-isoleucine, trace.(i) The valine fraction also contained α -aminobutyric acid (c. 3 μ moles). Since this fraction was inert on treatment with D-amino-acid oxidase, it probably contains only L- α -aminobutyric acid.

(j) The possible presence of D- and/or L-alloisoleucine has not as yet been excluded.

to be meso-diaminopimelic acid, alanine, of which at least one-third was L, and glutamic acid, of which at least 85 per cent was D.

(2) Mycoside C of *Mycobacterium avium*. The mycosides, a new class of type-specific glycolipids of *Mycobacteria*, have recently been described¹⁴. The results reported here include two mycoside C fractions Jav 5 and Jav 4. Jav 5 was eluted from a silicic acid column by chloroform-methanol (95:5) and had the following properties: m.p. 210°, $[\alpha]_D = -34^\circ$ (c = 2.0 per cent in chloroform). The analysis was: C, 62.16; H, 8.76; N, 4.35; OCH₃, 5.52; acetyl, 5.50 per cent. (C₅₆H₁₁₃N₅O₂₄ requires: C, 61.84; H, 8.89; N, 4.51; 3 OCH₃, 5.86; 2 acetyl, 5.54). Jav 5 appears to be a pentapeptide linked to a hydroxy acid of approximate composition C₃₂H₄₄O₈, the whole being linked to 3 molecules of partially O-methylated 6-deoxyhexoses containing two O-acetyl groups¹⁷. Jav 4 was isolated from the same extract as Jav 5 by elution from silicic acid with chloroform-methanol (94:6) and had the following properties; m.p. > 200°, $[\alpha]_D = -44^\circ$ (c = 1.9 per cent in chloroform). The per cent analysis was: C, 58.68; H, 8.57; N, 3.82; OCH₃, 6.62; acetyl, 6.90 (C₇₈H₁₃₁N₅O₂₈ requires: C, 59.07; H, 8.35; N, 4.48; 3 OCH₃, 5.87; 2 acetyl, 5.43). The probable structure of Jav 4 is a pentapeptide linked to a hydroxy acid of approximate composition C₃₄H₄₈O₈, the whole being linked to 4 molecules of partially O-methylated 6-deoxyhexoses containing two O-acetyl groups¹⁷.

(3) Mycoside C of *Mycobacterium marinum*. This substance (m.p. 198-200°, $[\alpha]_D = -31^\circ$ in chloro-

form, C, 64.65; H, 8.52; N, 4.70; OCH₃, 5.02; acetyl, 6.53 per cent) was isolated by Michel and Chaput¹⁹ (Laboratory of Biochemistry, Faculté Catholique, Lyon) from a strain isolated by Sister Marie-Suzanne and Penso¹⁹ from a leproma and now classified as a non-photochromogenic or avian strain.

(4) Peptido-lipid of *Nocardia asteroides*. Results are given for two separate preparations of the peptido-lipid of this organism²⁰.

Each sample was hydrolysed in 6 N hydrochloric acid at 105° for 24 hr. After evaporation to dryness *in vacuo*, the hydrolysate was dissolved in a small amount of water and placed on a 'Dowex-50 (H⁺)' column (9 × 850 mm., 200-400 mesh). The column was developed successively with 1, 2.5, and 4 N hydrochloric acid⁴, and the effluent collected in 5-ml. fractions. Aliquots of each fraction were analysed by the ninhydrin method of Yemm and Cocking²¹. The ninhydrin-positive fractions were concentrated *in vacuo* to dryness and the residues dissolved in 5 ml. of water and analysed. The results are given in Table 1.

Table 2. PAPER CHROMATOGRAPHY OF THE 'THREONINE' FRACTIONS OF THE MYCOSIDES OF *M. avium* AND *M. marinum*

Compound	R* (allothreonine)
DL-Allothreonine	1.00
Jav 4 'threonine'	0.99
Jav 5 'threonine'	0.99
<i>M. marinum</i> 'threonine'	0.97
DL-Threonine	1.39
DL-Serine	0.62

* Solvent system: upper phase of n-butanol:water:acetone:concentrated ammonia (200:150:25:25) (ref. 27). Due to variability in absolute R* values, values are given relative to allothreonine. R* (allothreonine) = 0.11-0.13

The 'threonine' fractions from the 'Dowex-50' chromatography of the hydrolysates of the mycosides of *M. avium* and *M. marinum* were chromatographed on paper and showed only a single ninhydrin-reacting spot corresponding in position to allothreonine (Table 2) and no serine or threonine. Since D-allo-threonine is attacked by D-amino-acid oxidase²², the configuration of the allothreonine was determined by this method (Table 1). That the substance was eluted from the column in the correct position for allothreonine was demonstrated by the overlapping emergence of threonine and allothreonine, the former slightly preceding the latter, when a mixture of these compounds was chromatographed on a 'Dowex-50' column and then eluted with 1 N hydrochloric acid.

The results demonstrate the widespread occurrence of D-amino-acids in the peptido-lipids and peptidoglyco-lipids of members of the order Actinomycetales. The alanine of 'Wax D' of *M. tuberculosis* var. *hominis* was found to be 1/3 D and the glutamic acid 78 per cent D, values essentially in agreement with those previously reported¹⁴. It is probable that the glutamic acid of this substance is completely of the D-configuration and that a certain amount of L-glutamic acid may have arisen from racemization during hydrolysis¹⁴. The mycosides of *M. avium* and *M. marinum* are unusual in that all the amino-acid components (alanine, allothreonine, and phenylalanine) possess the D-configuration. An additional unusual feature in these substances is the occurrence of D-allo-threonine, a compound not hitherto reported in a natural product. D-Allothreonine would result from racemization of the α -carbon atom of L-threonine, and this may be the pathway by which it is formed by the micro-organism. The peptido-lipids of *N. asteroides* differ considerably in composition from the mycosides. They contain threonine, valine and proline, all of the usual L-configuration, and alanine, which appears to be 2/3 D. The composition with regard to leucine and isoleucine has not been completely clarified. It is clear that there are only negligible amounts of L-leucine and of L-isoleucine present. The discrepancy between total leucine plus isoleucine as determined by ninhydrin and D-leucine plus D-isoleucine as determined by D-amino-acid oxidase would suggest the presence of L-alloisoleucine. These results also do not exclude the possibility of the presence of D-alloisoleucine.

leucine. Experiments to clarify this point are in progress.

We (M. I. and E. E. S.) wish to acknowledge the technical assistance of Mrs. Geraldine Tomlinson and Miss Helene Schenker, and support (in part) by a grant (E-1575 and 3134) from the United States Public Health Service. The work of the French group has been supported (in part) by a grant (E 28-39) from the National Institute of Allergy and Infectious Diseases, United States Public Health Service.

NEW PATHWAYS IN THE OXIDATIVE METABOLISM OF AROMATIC COMPOUNDS BY MICRO-ORGANISMS

By DR. S. DAGLEY

Department of Biochemistry, The University, Leeds

AND

PROF. W. CHARLES EVANS and D. W. RIBBONS*

Department of Agricultural Chemistry, University College of North Wales, Bangor

THERE exists a restricted number of pathways open for the breakdown of naturally occurring aromatic amino-acids in mammalian metabolism; inherited blocks in these have greatly influenced the development of our concepts of biochemical genetics¹.

Micro-organisms, however, are the main agents which release organic carbon locked up in benzenoid

structures by the plant world. Although they display a notorious versatility in this respect, only two methods of cleavage of the aromatic nucleus by microbial enzymes have been clearly demonstrated, until very recently. These are: (1) Oxidative fission of the bond between carbon atoms bearing the hydroxyl groups of an *o*-dihydroxyphenol (for example, Fig. 1a and b): catechol $\rightarrow$ *cis-cis*-muconic acid by pyrocatechase^{2,3}; protocatechuic acid $\rightarrow$

* Present address: Department of Biochemistry, The University, Glasgow.

cis-cis- β -carboxymuconic acid through the action of protocatechuic acid oxidase⁶. β -Oxoadipic acid is eventually produced in both these cases^{6,7}, which is then enzymically split to acetyl-coenzyme A and succinate, to be metabolized by reactions of the tricarboxylic acid cycle^{8,9}. This ring cleavage mechanism appears to play little or no part in mammalian metabolism. (2) Rupture of the bond between the carbon atom bearing a hydroxyl and an adjacent carbon atom carrying a carbon side-chain or carboxyl (for example, Fig. 2): homogentisic acid $\rightarrow$ maleyl-acetoacetate by homogentisicase^{10,11}; gentisic acid $\rightarrow$ maleyl-pyruvate by gentisicase¹²⁻¹⁴. This method is common to micro-organisms and mammals.

It appeared until recently that the main problems of interest in the catabolism of aromatic compounds by the lower organisms were those concerned with unexplored reaction sequences leading to the already known modes of ring-fission. Work at Leeds and Bangor has now made it clear that this view is much too limited; the established mechanisms of disruption of the aromatic ring, and subsequent reactions leading from the benzene nucleus to the citric acid-cycle, are by no means ubiquitous in their occurrence. In many soil bacteria, pathways of dissimilation of aromatic compounds exist which are radically different from those previously described.

Furthermore, the clear separation, as in Fig. 1a and b, of known channels cannot now be justified for all species of microbes, for example, enzyme systems from *Neurospora crassa*⁵, some *Pseudomonads*⁴, a *Vibrio* (0/1)¹⁵, and *Nocardia*¹⁶, all split protocatechuic acid to *cis-cis*- β -carboxymuconic acid from which

they afterwards produce β -oxoadipic acid, but the intermediary steps employed may differ somewhat. Moreover, the preliminary steps by which various aromatic compounds are converted to the compound which undergoes fission (that is, catechol, or protocatechuic acid, etc.) also prove to be more diverse than hitherto suspected, since an anaerobic decarboxylase has been discovered in some organisms^{17,18}, whereby a carboxyl group attached to the benzene nucleus is replaced by hydrogen.

Throughout this work, summarized here, both departments have benefited by a free exchange of information and biochemicals.

New Modes of Aromatic Ring-fission by Bacteria

(1) *Cleavage of protocatechuic acid by a new enzyme*—'protocatechuic acid 4:5-oxygenase': Dagley and Patel¹⁹ disrupted cells of a *Pseudomonas* grown with *p*-cresol as carbon source, the cell-free extract oxidized each mole of protocatechuate with the uptake of 1 mole of oxygen, but no carbon dioxide was liberated. Similar extracts of *Vibrio* 0/1¹⁵ also oxidized protocatechuate; 1 mole of oxygen was utilized, 1 mole of carbon dioxide was evolved, and β -oxoadipate was produced. In the case of the *Pseudomonas* system the product was a white, crystalline, dibasic acid, m.p. 235°, shown by Trippett, Dagley and Stopher²⁰ to be 2:4-lutidinic acid. The formation of the nucleus of pyridine as a consequence of oxidizing that of benzene was surprising; the realization that it had occurred was delayed by the coincidence that the percentage of carbon and hydrogen in lutidinic acid monohydrate is practically

Fig. 1. Oxidative fission of o-dihydroxyphenols by some micro-organisms. a, Pathway of dissimilation of catechol by some *Pseudomonads*; b, pathway of dissimilation of protocatechuate by *Neurospora crassa*

the same as that for a compound formed from 1 mole of protocatechuic acid and 1 mole of oxygen. Stopher *et al.*²⁰, using dialysed enzyme extracts of this *Pseudomonas*, showed that the initial product formed from protocatechuate was an acid possessing reactive carbonyl groups, and with an absorption spectrum shown in Fig. 3a. Ribbons and Evans²¹ followed this reaction in a respirometer, and as soon as it reached completion, extracted the keto-acid into ethyl acetate. It was re-extracted into dilute aqueous sodium hydroxide or carbonate, giving a characteristic yellow colour to the solution (reminiscent of ketonol tautomerism), which persisted. When dilute ammonia, however, was used, the yellow colour initially produced vanished within a few minutes, and a new compound was formed having spectrographic and chromatographic properties identical with 2:4-lutidinic acid. It is clear, therefore, that in the original experiments of Dagley and Patel¹⁹, this compound was formed by a non-enzymic reaction between the initial product of ring-fission and the ammonium ion, present accidentally in the cell-free extract, since ammonium sulphate had been used for its fractionation. These facts support the formula, α -hydroxy- γ -carboxymuconic semialdehyde (6-formyl-4-carboxy-2-oxohex-4-enedioic acid) we assign to the intermediate. It gives an acidic bis-2:4-dinitrophenylhydrazone, m.p. 170–2° (decomp.) and is somewhat unstable on recrystallization (Found: C, 39.8, 43.5; H, 3.4, 3.8; N, 19.2, 20.6; $C_{11}H_{14}N_2O_{11}$ requires C, 41.8; H, 2.6; N, 20.6 per cent).

When a non-dialysed cell-free preparation of this *Pseudomonas* is used to oxidize protocatechuate, α -hydroxy- γ -carboxymuconic semialdehyde is further metabolized to give a compound containing an additional carboxyl group, but the carbonyl groups have now disappeared. This second acid has a characteristic absorption maximum at 284 m μ and forms a *p*-bromophenacyl derivative (tri-ester) m.p. 101–2°; the fact that it appears without any further gaseous exchange supports the view that an internal oxidation-reduction is involved, to give 2-hydroxy-4-carboxy-2:3-dihydromuconic acid (5-

hydroxy-3-carboxyhex-2-enedioic acid). Concentrated, dialysed enzyme extracts degrade protocatechuate further, with the production of pyruvate as one end-product. In the presence of sodium arsenite ($5 \times 10^{-3} M$) and/or pyridine-3-sulphonic acid ($2 \times 10^{-3} M$), whole cells oxidize protocatechuate with substantial accumulation of pyruvate and oxaloacetate. The suggested sequence of reactions of the new pathway are depicted in Fig. 4. The fission proposed for 2-hydroxy-4-carboxy-2:3-dihydromuconic acid has not been demonstrated for cell-free systems; this investigation is in progress.

The two different ring-cleavage mechanisms of protocatechuic acid may be followed stoichiometrically in an automatic titrator, as shown in Fig. 5a and b with the following results:

Dialysed, cell-free preparations from organisms employing the 3:4-split produce from protocatechuate two equivalents of acid, with the formation of *cis-cis*- β -carboxymuconate; undialysed extracts produce approximately 1.3 equivalents with stoichiometric formation of β -oxoadipate (one carboxyl group having been lost through decarboxylation).

Dialysed, cell-free preparations from microbes performing the 4:5-split acting on protocatechuate, give rise to one equivalent of acid with the formation of α -hydroxy- γ -carboxymuconic semialdehyde ($\lambda_{\max}$ 293 m μ (acid); 410 m μ (alkali)); undialysed extracts metabolize this keto-acid further, with the appearance of a second acid equivalent, corresponding to 2-hydroxy-4-carboxy-2:3-dihydromuconate ($\lambda_{\max}$ 284 m μ).

(2) *Cleavage of catechol by a new enzyme—'catechol 2:3-oxygenase'*: The degradation of catechol by two strains of Gram-negative bacteria has been investigated by Dagley and Stopher²¹. One was supplied by Dr. Eileen Pankhurst, London Research Station of the Gas Council, and readily grows with *m*-cresol as sole carbon source; the other was isolated from garden soil, and utilizes *o*-cresol. Cell-free extracts from either organism oxidized 1 mole of catechol with the uptake of 1 mole of oxygen, but no carbon dioxide was evolved. During the reaction a transient yellow colour was produced, shown to be due to an

Fig. 2. Oxidative fission of *p*-dihydroxyphenols by micro-organisms and mammals

acidic intermediate; it gave an immediate bright orange colour with *o*-dianisidine (aldehyde test), and formed a *bis*-2:4-dinitrophenylhydrazone derivative. The keto-acid absorbed strongly at 373 m μ in neutral or alkaline solution; in acid this absorption and the yellow colour were abolished, and another peak appeared at 317 m μ (Fig. 3b). Clearly, this intermediate has similar properties to α -hydroxy- γ -carboxymuconic semialdehyde, although it differs in being much less reactive towards ammonia, since α -picolinic acid is formed only after standing with ammonium hydroxide for two days at room temperature¹⁰. Fortunately, it proved possible to isolate the intermediate itself. Stopher observed that when cell-free extracts of the *o*-cresol-utilizing *Pseudomonas* were maintained at 53° for 10 min., the enzymes that degraded the intermediate were destroyed, but not those involved in its production from catechol. By use of heat-treated extracts, a small quantity of an orange-coloured solid was isolated, which on analysis gave: C, 50.9; H, 4.3. α -Hydroxymuconic semialdehyde (6-formyl-2-oxohex-4-enoic acid), C₆H₆O₄, requires C, 50.8; H, 4.2 per cent. When reduced with platinum in ethanol, reactions for carbonyl groups were no longer given, and 3 moles of hydrogen were taken up per mole of substance, as required for reduction of two double bonds and one aldehyde group.

Untreated extracts gave pyruvate as one end-product of catechol oxidation, and the reaction could be followed in a spectrophotometer by measurements of absorption at 275 m μ ($\lambda_{\max}$ for catechol) and at 430 m μ where the intermediate absorbs (though not maximally) but catechol does not. During the course of this experiment the intermediate was rapidly formed and then degraded; *cis-cis*-muconic acid, present in a control vessel, was not attacked by the extract (Fig. 6). A heat-treated extract which decomposed catechol also attacked 4-methylcatechol to form an intermediate with an absorption spectrum similar to that from catechol ($\lambda_{\max}$ = 378 m μ) but differing in some details. Various other phenolic compounds were not attacked.

For certain strains, notably the *Pseudomonas* of Dagley and Patel¹¹, ferrous ions can readily be shown to be a requirement for the enzymes catalysing the new mode of ring-fission but in other cases, the iron, if it should prove to be essential, is very strongly bound to the protein and cannot be removed by dialysis.

The product of ring-fission of catechol (α -hydroxymuconic semialdehyde) has already been encountered in work with mammalian systems. Wiss¹², and Mehler¹³, have shown that an enzyme from liver oxidizes 3-hydroxyanthranilic acid to a derivative of muconic semialdehyde (Fig. 7). On standing in acid, carbon dioxide and ammonia are lost to form a compound, the spectrum of which agrees with that shown in Fig. 3b, and is similarly affected by changes in pH (ref. 23). Dr. Mehler kindly supplied us with a small amount of this compound; although not pure, material present which absorbed strongly at 375 m μ was rapidly decomposed by our cell-free extracts.

One product of the action of crude bacterial extracts on α -hydroxymuconic semialdehyde has been identified as pyruvate (Fig. 7), but details of the degradation are not yet known. By analogy with the reactions of Fig. 4 it might be suggested that the semialdehyde is first converted into 2-hydroxy-2:3-dihydromuconate, although in this case extracts have not been

obtained which accumulate this compound. It is conceivable that 2-hydroxy-2:3-dihydromuconate would then undergo a hydrolytic split between carbon atoms 3 and 4 to produce malonic semialdehyde and lactate; a coupled oxidation-reduction would then produce pyruvate and β -hydroxypropionate.

Proctor and Scher¹⁴ have recently investigated the metabolism of benzoate by a *Rhodospseudomonas* strain, and found that the pathway of degradation by this organism is different from those described to date, but consistent with the following sequence: benzoate $\rightarrow$ protocatechuate $\rightarrow$ catechol $\rightarrow$ an unidentified α -oxo acid which appears to be similar to α -hydroxymuconic semialdehyde. Extracts of this organism degraded catechol to an α -oxo acid only when hydrogen peroxide was added; oxygen would not be substituted. This system appears to differ therefore

Fig. 3. Absorption spectra of the new ring fission products. *a*, Initial ring fission product (α -hydroxy- γ -carboxymuconic semialdehyde) of protocatechuate oxidation by protocatechuate 4:5-oxygenase. In acid (—●—), in alkali (—○—); molar extinction coefficient at $\lambda_{\max}$ = 410 m μ is 29,000. Also of the further metabolite, 2-hydroxy-4-carboxy-2:3-dihydromuconate (—△—), molar extinction coefficient at $\lambda_{\max}$ = 284 m μ is 5,000. Molar extinction coefficients are calculated on the basis of protocatechuate oxidized.

b, Initial ring fission product (α -hydroxymuconic semialdehyde) of catechol oxidation by catechol 2:3-oxygenase. In acid (—●—), in alkali (—○—); molar extinction coefficient at $\lambda_{\max}$ = 378 m μ (pH 7.3) is 29,700, calculated for a solution of the purified compound containing 2.7 μ gm./ml.

Fig. 4. Suggested new pathway of protocatechuate oxidation by micro-organisms which possess the protocatechuate 4:5-oxygenase system

from both pyrocatechase and catechol 2:3-oxygenase, and may well be yet another ring-fission enzyme. Their observations, published in abstract form, are complicated, since whole cells in the presence of

oxygen or hydrogen peroxide produced a β -oxo acid (identity not disclosed) from catechol.

(3) *Variations in the subsequent pathway of cis-cis- β -carboxymuconic acid*: Several microbial species metabolize protocatechuate through *cis-cis- β -carboxymuconate* to the common intermediate β -oxo-adipate; it now transpires that the intervening steps are not identical in all cases. Gross, Gafford and Tatum⁵, using 2:6-¹⁴C₂-labelled protocatechuk acid, showed that the carbonyl-C of β -oxoadipate produced by a *Neurospora crassa* enzyme system originated solely from C-6 of protocatechukate, whereas using a *Pseudomonas fluorescens* system (strain A, 3.12, Stanier) it was randomly derived from C-1 and C-6 of this substrate. This *Pseudomonas* route diverges from the *Neurospora* pathway (shown in Fig. 1b) after the *cis-cis- β -carboxymuconate* stage, since β -carboxymuconolactone was not attacked; *cis-cis*-muconate and muconolactone were not degraded by either of these enzyme systems. The tracer results for this *Pseudomonas* pathway imply the formation of a symmetrical precursor to β -oxoadipate, which

Fig. 5. A comparison of acid production during ring fission and further metabolism of protocatechuate by: a, protocatechuk acid oxidase; and b, protocatechuk acid 4:5-oxygenase

The reaction cuvette contained enzyme solution (sonic extracts in distilled water, 1 ml.) as indicated, and distilled water (4 ml.), brought to pH 7. Temperature, 80°. Reactions were initiated by addition of protocatechukate (10 μ moles in 1 ml. water, previously neutralized to pH 7). The micro-burette contained 0.1 N sodium hydroxide, and automatic additions during reaction were recorded graphically (Radiometer, Ltd., Copenhagen)

Fig. 6. Spectrophotometric assay of catechol oxidation by the catechol 2:3-oxygenase system. Optical density due to catechol at 275 μ (—O—); optical density due to α -hydroxymuconic semialdehyde at 480 μ (—●—)

Fig. 7. Suggested new pathway of catechol oxidation by micro-organisms possessing the catechol 2:3-oxygenase system. The formation of α -hydroxymuconic semialdehyde from catechol, and its relation to the ring fission product of 3-hydroxyanthranilate by the liver enzyme, is indicated.

Elsdon and Peel²⁴ suggested might be the dilactone of *cis-cis*-muconic acid (butanolido- β - γ - β' -butanolide). Cain, Ribbons and Evans²⁵ found that this dilactone gave rise to β -oxoadipate with extracts from another *Pseudomonas* strain and *Vibrio* 0/1 induced to protocatechuate. At slightly acid, neutral and alkaline pH, however, the dilactone itself underwent a non-enzymic rearrangement to muconolactone. Moreover, muconolactone also produced β -oxoadipate with these enzyme systems. The spontaneous hydrolysis of the dilactone to muconolactone followed by enzymic attack on this product is responsible for apparent attack on the dilactone itself; this dilactone cannot therefore be an intermediate in these particular systems, but $\beta\beta'$ -dihydroxyadipate and carboxydilactone are further possibilities to be explored. Cain¹⁵ has shown that muconolactone, which he rigidly identified, accumulated when heat-treated extracts of *Vibrio* 0/1 grown on *p*-hydroxybenzoate oxidized protocatechuate with consumption of 1 mole of oxygen and the evolution of 1 mole of carbon dioxide per mole of substrate. From these results it is probable that muconolactone is an intermediate in the conversion of *cis-cis*- β -carboxymuconate to β -oxoadipate by *Vibrio* 0/1 and by some, but not all, *Pseudomonas* strains (Fig. 8).

Yet another route from *cis-cis*- β -carboxymuconate to β -oxoadipate is taken by *Nocardia erythropolis* according to the work of Cain and Cartwright¹⁶.

A lactone-like intermediate is produced having $\lambda_{\max}$ at 215–218 m μ ; it differs from any known lactone of these series, and awaits identification.

(4) *Diversity of pathways in the oxidative metabolism of aromatic compounds prior to ring fission.* Hayaishi and Stanier²⁶ showed that there were two distinct pathways of tryptophan metabolism among the *Pseudomonads*. Most organisms oxidize this amino-acid through kynurenine, anthranilate and catechol; some strains diverge from this sequence at the kynurenine stage, producing kynurenic acid, the subsequent fate of which has been partially clarified²⁷.

Microbial dissimilation of phenylacetate shows an analogous dichotomy, as demonstrated by Kunita; one strain of *Pseudomonas fluorescens* produces homoprotocatechuate²⁸ from this substrate, while another appears to take the homogentisate route²⁹.

The pathways employed for the utilization of the benzoates among microbial species and strains prior to ring-fission, discovered to date, are illustrated with references in Fig. 9; a more remarkable diversity than was at one time supposed is clearly evident.

The enzymic transformations involved in these reactions are hydroxylations or perhydroxylations (followed by dehydrogenation), and decarboxylations or oxidative decarboxylations. The particular route taken by a micro-organism capable of utilizing an aromatic compound will presumably depend on its genetic potential, coupled with the influence of

Fig. 8. Pathway of dissimilation of protocatechuate by *Vibrio* 0/1. The carboxydilactone step is hypothetical.

Fig. 9. Diversity in metabolism of the benzoates by micro-organisms

environment, for the syntheses of the relevant enzymes.

Micro-organisms which degrade polycyclic aromatic compounds appear to employ a stepwise, end-ring attack (for example, naphthalene, anthracene, phenanthrene and their derivatives)³²⁻⁴⁰. The discovery of this new method of ring cleavage now makes it probable that there exist several alternative routes for the metabolism of condensed ring systems. Similarly, the metabolism of herbicides of aromatic nature by soil microbes^{40, 41} may well show diversity due to species and/or strains.

Although we have no statistics as to the relative prevalence of the various modes of ring fission, bacteria which employ all of them abound in the soil.

We wish to thank the Department of Scientific and Industrial Research and the Agricultural Research Council for their financial support.

GEOPHYSICS

Formation of the Sporadic E Layer in the Temperate Zones

In a recent communication Heisler and Whitehead¹ noted that the fraction of time the critical frequency of the sporadic E layer ($f_o E_s$) exceeded 5 Mc./s. depended on the horizontal component of the Earth's magnetic field, increasing as the horizontal component increased. This relationship is consistent with sporadic E formation arising from a vertical gradient of horizontal movement of the neutral air. In a region where the gyro-frequency of the ions, ω_{Hi} , is less than their collision frequency, ν_i , it is possible to show that, if there is no vertical electric current and the net horizontal current is zero (a horizontal current at one height being cancelled by a reverse current at some other height), the vertical velocity of ions and electrons is given approximately by:

$$V_z \sim \frac{-\omega_{Hi} \cos \theta}{\nu_i} \cdot \Delta U_y$$

where θ is the dip angle and ΔU_y is the departure of the horizontal wind velocity at right angles to the Earth's magnetic field from the mean value in the region. A thin layer of ionization will form where V_z is zero but where the vertical gradient of V_z is large. The probability of such formation depends on $\omega_{Hi} \cos \theta$, which is proportional to the horizontal component of the Earth's magnetic field.

Thus the global distribution of E_s in the temperate zones may be explained.

A more detailed analysis shows that at the height at which an E_s layer is already formed, ΔU_y , and hence V_z , remain nearly zero, independent of the horizontal winds. Thus the E_s layer continues to form at the same height. This explains the persistence of the E_s layer even when the horizontal winds leading to its original formation might be expected to have changed.

The detailed analysis will be presented elsewhere.

Telluric Current Micropulsations on Arctic Drifting Station Charlie

TELLURIC current recording equipment was operated on Arctic Drifting Station Charlie during the epoch October 15–December 31, 1959. The station was located on a 4-mile by 7-mile ice floe of quite uniform thickness, the thickness averaging perhaps 10 ft. The electrodes consisted of 8-ft. by 2-in. lead strips prepared from electric cable sheathing. Electrode pairs were cut from continuous lengths of

Fig. 1. Telluric current, Arctic Drifting Station Charlie, December 11, 1959

sheathing to assure identity of material in the two electrodes. No difficulty was experienced with contact potentials. The d.c. voltage never exceeded a few millivolts and was very steady. The electrodes were suspended in the sea just below the ice at a spacing of 1.082 km. The relatively long spacing was necessary because of the low mV./km. values experienced over the highly conducting sea water.

On December 11, 1959, micropulsations of less than 1-sec. period were recorded for an interval of more than 2 hr. On this date the floe was located at 75° 57' N. and 171° 01' W., which corresponds to geomagnetic co-ordinates of 70° 55' N. and 222° 33' E. During the afternoon of this day (0200–0240 U.T.) a very sensitive recorder, 2 mV. full scale on the 1.082 km. spaced electrodes, was operated to search for micropulsations. Even though this was a very quiet period, based on normal recording, it was necessary to return the pen to scale several times by inserting a voltage in the electrode lines. This trace is presented as Fig. 1. A slight widening of the trace is evident, but the effect is so small as to be inconclusive as an indication of the occurrence of micropulsations.

On returning to the laboratory in the evening a quiet auroral arc was observed. The arc extended to the horizons and passed through the zenith. The normal sensitivity telluric current recorders were essentially quiet, the normal condition during such an auroral display. The high-sensitivity recorder was reconnected to the electrodes and the trace of Fig. 2 recorded. It is impossible even on the original trace to discern the individual fluctuations. However, the upward motions of the pen were counted by visual observation for six 1-min. intervals, extended over an hour of the activity. These counts gave 70, 70, 70, 67, 68, and 70 cycles per minute. It was also noted that the rate of fluctuation tended to be very uniform throughout the activity. The amplitude of the pulsations ranged from 0.05 to 0.10 mV./km. The circumstances of the experiment assure beyond any reasonable doubt that these were natural micropulsations and not variations introduced by the instrumentation.

No previous record of telluric current micropulsations of this short period has come to my attention.

PHYSICS

Shock Excitation of Solid Aromatic Hydrocarbons

SHOCK excitation of a wide range of powdered inorganic solids (mainly metallic oxides) by helium-driven shock-waves in argon¹ has not only provided a powerful means of producing relatively clean spectra of astrophysically important diatomic molecules², but also has given some insight into the physical processes which take place when the powder particles undergo severe thermal transients. From the general observation that molecular spectra alone are excited (in the hot stagnant region behind the reflected shock wave) at low temperatures ($\sim 2,000^\circ\text{K}$), mixed molecular and atomic spectra are excited at intermediate temperatures ($\sim 5,000^\circ\text{K}$) and entirely

atomic spectra are excited at high temperatures ($\sim 10,000^\circ\text{K}$), and from other experimental considerations (refs. 1a and 1c), it is thought that a predominantly atomic vapour is evaporated from the solid inorganic surfaces, which, if the temperature is low enough, partially or completely recombines to form diatomic species. It is therefore a logical extension of this work to examine the variation with environmental temperature of the spectra from shock excitation of powdered organic materials, and in this communication experiments with benzene, naphthalene, and anthracene are discussed.

Greene³ has examined the spectra from shock excitation of the aliphatic vapours: (a) XCN ($\text{X} = \text{Br}, \text{Cl}$); (b) CX_2Y ($\text{X} = \text{H}, \text{F}$; $\text{Y} = \text{Br}, \text{I}$) and reports the presence of CN violet bands and C_2 Swan bands in the case of (a), and a carbon particle continuum, C_2 Swan bands, and a CH band in the case of (b). Fairbairn and Gaydon⁴ have reported spectra from the shock excitation of a much wider variety of aliphatic vapours, and find that the carbon particle continuum and the C_2 Swan bands predominate while OH and CN sometimes appear. They find no trace of CH even for molecules containing C and H. Johnson and Campbell⁵ report CH and C_2 bands in absorption through shock-heated benzene vapour.

In our experiments a few grams of each powdered solid to be studied were placed at the end window of a small shock-tube (except in the case of benzene, which was frozen on to the inner wall of the shock tube near the window by means of an external dry ice jacket). A series of spectra were photographed on a Hilger $f/4$ spectrograph over as large a range of calculated stagnant-region temperatures as possible. These temperatures are undoubtedly inaccurate as they take no account of the contamination of the argon with organic vapours. However, Parkinson and Nicholls (refs. 1d, 6) have shown that (in shock-excitation of inorganic solids) the rotational temperature of the CN molecule is only about 10–15 per cent lower than the calculated gas kinetic temperature, and in good agreement with the temperature inferred from the measured shock-speed. The shock tube was cleaned and recharged with organic material between each exposure.

In each case the main contributions to the spectra were the (0;0,1,2) (1;0,1,2,3) (2;0,1,2,3,4) (3;1,2,3,4,5) (4;2,3,5,6) (5;6) C_2 Swan bands, the (0;0,1) (1;1,2)

Table 1. SPECTRA FROM SHOCK EXCITATION OF SOLID BENZENE, NAPHTHALENE AND ANTHRACENE

Temperature range used	Benzene 4,900–8,440° K.			Naphthalene 3,890–13,000° K.			Anthracene 3,630–12,020° K.		
	Temp. of appearance	Temp. of maximum intensity	Comments	Temp. of appearance	Temp. of maximum intensity	Comments	Temp. of appearance	Temp. of maximum intensity	Comments
Atomic impurities (Na, Ca)	4,900°	6,990°	Present at lowest temp. Not present at 8,440°	3,890°	6,870°	Not present at 13,000°	—	—	—
C-particle continuum	—	—	Benzene not in powder form	3,890°	4,800°	Reaches low value at 6,900°, remains until 13,000°	3,630°	5,950°	Reaches low value at 6,850° and remains constant to 12,020°
C_2 Swan bands	4,900°	6,990°	Weak at 8,440°	4,800°	10,250°?	Constant to 13,000°	5,950°	6,350°	Weak at 12,020°
CN violet bands	4,900° (weak)	6,990°	Not present at 8,440°	6,080°	?	Gradual increase to 13,000°	4,970°	5,950°	Absent above 8,800°
OH 14316 Å. band	6,990°	?	Present at 8,440°	6,870°	?	Gradual increase to 13,000°	5,950°	6,350°	Absent above 8,800°

(2;2,3) (3;3,4) (4,5) (5,6) CN violet bands (nitrogen was an impurity in the argon), the (0,0) CH band ($\lambda 4315 \text{ \AA}$), and (except in the case of benzene) a carbon particle continuum the intensity and spectral range of which were extremely sensitive to temperature. The circumstances in which the various spectra appear are summarized in Table 1. The lack of carbon-particle continuum in the case of benzene is probably due to the fact that it is not powdered but a solid coating on the wall of the tube. In the case of the other two compounds, the powdered configuration and consequent large surface area gave greater chance for pyrolysis in the hot gas. Abundant solid carbon particles were present in the shock tube after each experiment.

There is a striking contrast between these entirely molecular spectra (except for a few atomic impurity lines due to sodium and calcium) over the entire temperature-range, and the smooth transition with increasing temperature from molecular to atomic spectra observed in the case of the inorganic compounds. It is therefore doubtful whether the same mechanism is operative in both cases. It seems more probable (in view of the much lower volatilization temperatures of the organic compounds) that the shock treatment causes evaporation of a molecular vapour which is pyrolysed to carbon at lower temperatures (possibly by Porter's acetylene mechanism⁷ confirmed by Greene, Taylor and Patterson⁸ for a number of simple hydrocarbon vapours). At higher temperatures reactions between the carbon vapour and other gases (nitrogen and hydrogen), present in the tube following pyrolysis, qualitatively explain the CH and CN spectra. Spectra of atomic carbon are not observed in the spectral range of our instrument because of the inaccessibility to thermal excitation (at the temperatures used) of the upper states of allowed transitions in C.

The Critical Phenomena between Solids and Fluids

IN the phase diagrams of simple pure substances, the unknown fundamental problem is only the upper limits of melting points. Is there any critical phenomena between solids and fluids? (Generally at their melting points solids change to gases without going through the liquid stage in the high-temperature and high-pressure range.)

Experimental research on this problem was begun by the late Sir Francis Simon and his school thirty years ago. Up to the present, investigations have been carried out up to 7,500 atm. for helium¹ and 10,000 atm. for nitrogen and argon², but there is no evidence of the existence of critical points. Therefore Prof. P. W. Bridgman³ and Prof. C. Domb⁴ and the others have been inclined to doubt the existence of this point. Profs. L. Landau and E. Lifschitz⁵ have also stated definitely there is no intermediate state between crystal and liquidus, for these states have distinct characteristics of internal symmetry.

As this problem is of the utmost importance for understanding the structure of liquids too, I wish to discuss the problem in connexion with my structural model of liquids⁶.

Recently, Prof. J. D. Bernal⁷ reached the important conclusion that "there is an absolute impossibility of forming a homogeneous assembly of points of volume intermediate between those of long-range order and closest packed disorder". Therefore, by the geometrical model with its static characteristics, the liquidus (disordered) state cannot truly change to the solid (ordered) state continuously. Meanwhile⁸ I have presented a simple structural model of liquids with dynamical characteristics, which is consistent with Bernal's model. From this model, the structure of liquids near their melting points is approximated by a quasi-face-centred cubic lattice in which there are many vacant sites occupying about 10 per cent of the structure, but these empty spaces are distributed through all the interstices, causing the disappearance of the long-range order of lattice. Therefore, if the concentration of vacant sites is increased up to several per cent in crystals at sufficiently high temperatures and pressures, the regular lattices of the crystals will be gradually distorted under these conditions, resulting in irregular liquid structures.

The free-energy change ΔG in going from the regular perfect crystals to this intermediate state at constant temperature and pressure is:

$$\Delta G = \Delta E + p \cdot \Delta V - T \cdot \Delta S \quad (1)$$

where ΔE , ΔV and ΔS are the changes of internal energy, volume and entropy respectively. Generally, the first and second terms of the right-hand side of equation (1) are positive, and the third is negative; and generally $\Delta G > 0$, corresponding only to the low concentration of vacant sites in crystals at melting points under ordinary pressures. But, in highly compressed condensed systems, if the equilibrium positions of the bottoms of molecular potential wells are higher than zero, which corresponds to the potential energy of free gas molecules (see Fig. 1), ΔE will become negative, and in the higher temperature range $-T \cdot \Delta S$ will also take large negative values, with the result that $\Delta G < 0$. Therefore in these highly compressed and high-temperature conditions the vacant sites will be produced spontaneously in crystals

Fig. 1. Intermolecular potential curve (a) and a potential well of a molecule in the condensed phase (b)

In general, the following formulae representing the intermolecular potentials ϕ is applicable to monatomic van der Waals' and metallic liquids, including spherico-symmetrical molecular liquids⁸:

$$\phi = -ar^{-m} + br^{-n}, \quad m < n$$

and

$$\frac{D}{r^*} = \left(\frac{m}{n}\right)^{1/(n-m)}$$

where r^* is the distance apart of molecules at the minimum potential and D is the distance at zero energy-level (see Fig. 1).

Fe	$3-4 \times 10^3$	8,000-4,000	3.9-3.5	40	4	7

* Values estimated by Ebert in ref. 8.

In 1954 the late Prof. L. Ebert⁸ estimated the critical temperatures T_c and pressures P_c of nitrogen, carbon tetrachloride and other gases by ingenious extrapolations from Bridgman's experimental data (see Table 1). From his values I have estimated the critical molar volumes V_c of nitrogen and carbon tetrachloride using Bridgman's data⁹ (see Table 1), and found that these values are a little smaller than the volume calculated from D and thus support my views. In an infinitesimal change of the intermediate state of critical regions, $\delta G = 0$ and (1) becomes:

$$T_c (\partial S / \partial V)_{P_c T_c} = P_c + (\partial E / \partial V)_{P_c T_c} \quad (2)$$

and we can explain approximately and verify this equation for nitrogen by using the data of Table 1 and my model.

Therefore, if ϕ is known, V_c can be calculated approximately. Next, by the extrapolation of experimental compressibilities and fusion curves, we can estimate P_c and T_c in an effort to make the above values consistent. This procedure is made easier by using the hypothesis that the non-dimensional quantity $P_c V_c / RT_c$ will not vary as widely in several substances. This hypothesis is supported by the fact that at the critical points between gases and liquids, it is 0.29 for the spherico-symmetrical van der Waals' gases, which have values of $n = 12$ and $m = 6$, and $0.46 \sim 0.77$ for mercury¹⁰, which has lower values of n and m than the above (see Table 2).

My estimated critical values are given in Table 1. For helium I used the value of ϕ from Johnston and Grilly¹¹, the fusion curve of Holland, Huggill and

Table 2. EXPERIMENTAL CRITICAL POINTS BETWEEN GASES AND LIQUIDS

	P_c (atm.)	T_c (°K.)	V_c (c.c./mol)	$P_c V_c / RT_c$	m	n
He	2.26	5.3	57.8	0.30	6	12
N ₂	33.5	126	90.2	0.29	6	12
Hg	1,640 ¹⁰	1,730 ¹⁰	67-40 ¹⁰	0.46-0.77	6 ¹¹	8 ¹¹

Jones¹ and the molar volume of Dugdale and Simon¹²; for potassium, ϕ ($m = 2$, $n = 4$) was from Birch¹³ and Gilvary¹⁴ and the data of Bridgman⁹; for iron ϕ ($m = 4$, $n = 7$) was from Furth¹⁵, the density estimated by Birch¹⁶ and Valle¹⁷, with experimental compressibility from Walsh, Rice, McQueen and Yarger¹⁸, and the fusion equation from Strong¹⁹.

My values for helium are about twice as large as those of the previous experimental region. The values for potassium and iron only have a meaning concerning the order of magnitudes owing to the low reliabilities of ϕ and other data, and owing to their body-centred cubic structure, which is not the close-packed structure. But it is interesting that the values for iron are near those for the Earth's core. Moreover, on the surface of the Earth's core, putting $P = 1.4 \times 10^6$ atm., $V = 5.74$ c.c./mol. for iron and $T = 2,600^\circ$ K., which is the melting point of iron calculated from Strong's equation¹⁹, we obtain a non-dimensional quantity $PV/RT = 37.7$, very near that of the estimated critical point of iron. Hence it seems likely that there is an internal relation between the critical phenomena and the fluid characteristics of the Earth's core.

In any event, it will be valuable to examine, by modern techniques, the critical limits of the melting points of nitrogen or helium at pressures about twice as high or more as those used in previous experiments.

Velocity of Ultrasonic Waves in Aqueous Solutions of Zinc Halides

Zinc and cadmium belong to sub-group II of the Periodic System. Their compounds exhibit properties characteristic of the second group. Deviations from the normal thermodynamic behaviour have been reported in the case of halides of these metals¹.

Investigation by ultrasonic radiation^{1,2} of aqueous solutions of cadmium halides showed interesting deviations from the normal behaviour of electrolytic solutions. Hence, it is expected that zinc halides would also exhibit similar anomalies.

Ultrasonic velocity as a function of concentration has been studied using a variable-path, single-crystal interferometer, working at 780 kc/s. Velocity measurements were made at $32 \pm 0.5^\circ \text{C}$, and are accurate to ± 0.15 per cent.

Experimental results showing the variation of velocity with molar concentration are presented in Fig. 1. All the halides show exceptional behaviour. In the case of zinc chloride, the velocity increases with concentration up to 0.25 M, after which it decreases continuously, reaching a value of 1,503 m/s. at 1.5 M. Thereafter the velocity remains constant in the concentration-range studied (up to 2.5 M). Zinc bromide also exhibits a similar tendency, but to a lesser degree; up to 0.5 M the velocity remains practically constant and thereafter it decreases. Zinc iodide shows a continuous decrease with increasing concentration.

Fig. 1

Balachandran³ has studied the ultrasonic behaviour of zinc iodide in the concentration-range 0–0.5 M. His results also indicate decrease of velocity of sound with increasing concentration.

Adiabatic compressibility decreases with increasing concentration in all three cases. At any molar concentration, the decrease in compressibility of water is a maximum in the case of iodide and a minimum in the case of chloride. It is to be noted that this order is the reverse of that found among cadmium halides⁴.

Full details of this investigation will be published shortly. I thank Dr. J. Bhimasenachar for his encouragement and helpful discussions.

The Unit of Neutron Flux

HAVING lectured for several years on the physics of nuclear reactors, we have often felt the need for a unit of neutron flux. It is comparatively easy to write "ns per cm.² per sec.", but much more clumsy to speak aloud the expression "neutrons per square centimetre per second" while lecturing.

We have adopted the name 'chad' as the unit of neutron flux in our lectures, in honour of Sir James Chadwick, and we would like to suggest that this name becomes the accepted unit, defined as follows:

$$1 \text{ chad} \equiv 1 \text{ neutron per cm.}^2 \text{ per sec.}$$

Electron Microscope Out-of-focus Image of the Edge of a Crystal Lattice

IN 1957, Cowley and Moodie¹ pointed out, theoretically and by optical analogue experiments, that so-called Fourier images can be observed in out-of-focus images of a periodic object. According to them, Fourier images are interference fringe systems arising from the transmitted primary and several diffracted waves, and are a series of images in particular planes both in front of and behind the object and having the same geometrical form as the periodic object. In electron microscope images, passing through the focus, of copper-phthalocyanine, Komoda² observed that the periodic structure in the image appeared again after it had become diffuse. He concluded that the periodic structures appearing at a different focus are the Fourier images of the crystal lattice predicted by Cowley and Moodie. In the out-of-focus image of copper-phthalocyanine crystal taken by Komoda, we have detected a few extra lines outside an edge of the crystal (see Fig. 1). Such lines are not explicable by the theory of Cowley and Moodie. By using a light optical analogue, it has been shown that these lines are due to effects arising from the termination effect of the Fourier images and Fresnel diffraction of electron waves at the edge of the crystal.

Fig. 2 is a schematic diagram which demonstrates the Fourier images on the exit side of a grating for

Fig. 1. Fringes of copper-phthalocyanine crystal for in-focus (a) and out-of-focus (b) image. By courtesy of Komoda. ($\times 483,000$)

the case of $n = 0, \pm 1$ waves, where n is the order of reflexion. The spacing of the fringes is equal to that of the grating, and the intensity alternates as the distance from the grating becomes larger, with increase in order of the Fourier images, $N = 0, \pm 1/2, \pm 1, \pm 3/2, \dots$ (negative sign indicates a virtual image). From Fig. 2 it can be seen that the number of fringes increases as the Fourier image of higher order is focused; for example, in the Fourier image of $N = 1/2$ one more fringe appears than in the image of $N = 0$. In the out-of-focus image of a crystal edge, Fresnel diffraction takes place at the edge both for beams which pass inside and outside of the crystal. Then the character of the fringes is slightly changed from that expected from Fig. 2. These effects can easily be demonstrated optically by using a plane grating and light.

Fig. 2. Mode of interference of the electron waves passing through the lattice

In our demonstration, a plane grating of $66\text{-}\mu$ spacing with an edge was irradiated by an almost parallel light beam of wave-length $4900\text{\AA}$. This corresponds to a thin crystal of $6.6\text{\AA}$ lattice spacing with an edge, which is irradiated by a 60-keV electron beam. Figs. 3a and b are images of the plane grating obtained by focusing on the Fourier images $N = 0$ and $N = 1/2$ respectively. One more line is clearly formed outside the grating, and two more faint lines are also detectable. From this experiment, we can expect in the out-of-focus image of the crystal lattice many more extra lines would be formed outside the crystal than are predicted by the Fourier image theory. In Fig. 1, three additional lines are detectable and the amount of de-focus,

Fig. 3 (a) and (b) are the fringes in the Fourier images of $N = 0$ and $N = 1/2$ respectively. In (b) one strong and two faint fringes can be observed outside the grating

which is estimated from the Fresnel fringe at the edge of the contaminating substance, is about 0.5μ , which corresponds to $N \approx 1/2$. The number of extra lines outside the crystal agrees with that in the optical model.

In a real crystal the intensity of beams reflected by the lattice planes is expected to vary according to the thickness and the inner potential of the crystal and to the amount of deviation from the Bragg angle, and a full analysis using the dynamical theory, taking these quantities into account, will be published shortly.

We thank Prof. K. Tanaka, Prof. K. Kobayashi and Dr. J. W. Menter for their helpful discussions.

METALLURGY

Potential-Time Curves obtained during the Stress Cracking of Metals

WE have investigated some of the electrochemistry of two 12 per cent chromium martensitic steels while undergoing cracking in acid media. Since it is known that these steels can be made to crack through hydrogen embrittlement as well as by stress corrosion, we were curious as to the cause of cracking in 1 per cent hydrochloric acid with 1 per cent dissolved selenium dioxide. Following the procedure of Brown¹, increasingly larger polarizing currents, both anodic and cathodic, were applied to stressed beam specimens to determine which reaction hastened the time to failure. From these results we concluded that the cracking in this medium was by hydrogen embrittlement. Further proof was obtained by substituting sulphuric acid for hydrochloric acid (to eliminate the possible stress corroding influence of the chloride ion) without any change in the pattern of results. Simultaneously with our tests on the effect of applied currents on time to fracture, potential-time curves were automatically recorded. The rather unusual changes in potential we observed are primarily the reason for this communication.

Potential-time curves have been plotted by several investigators studying the stress corrosion cracking of metals²⁻⁴. We are not aware of similar curves for hydrogen cracking. As a means of reference we have summarized the characteristics of potential-time curves obtained when austenitic stainless steels undergo stress corrosion cracking in magnesium chloride and mild steels stress-crack in boiling nitrate solutions. Certain of these features are also duplicated by aluminium and magnesium alloys in chloride environments.

(1) There is a gradual rise in potential in the noble direction immediately after the specimen is exposed to the cracking medium. The shape of this portion of the curve is independent of applied load.

(2) After a limiting potential is reached, breaks may occur in the potential-time curves when the

specimen is under load. These breaks are evidenced by very rapid drops in potential to a more active value and fairly rapid return to the 'normal' value.

(3) When the specimen finally fractures by stress corrosion, there is a very rapid drop to a more active potential.

(4) Application of cathodic current delays or possibly prevents failure. Anodic polarization may hasten time to failure.

The following outline describes the almost completely opposite effects found with the 12 per cent chromium steels: A, carbon, 0.129 per cent; manganese, 0.55 per cent; silicon, 0.40 per cent; phosphorus, 0.012 per cent; sulphur, 0.012 per cent; chromium, 12.15 per cent; nickel, 0.38 per cent; molybdenum, 0.02 per cent; copper, 0.11 per cent; B, carbon, 0.050 per cent; manganese, 0.63 per cent; silicon, 0.26 per cent; phosphorus, 0.012 per cent; sulphur, 0.017 per cent; chromium, 11.73 per cent; nickel, 1.76 per cent; molybdenum, 0.01 per cent; copper, 0.06 per cent; stressed to approximately 80 per cent of their yield strengths in a room temperature solution of 1 per cent selenium dioxide in 1 per cent hydrochloric acid (or 5 per cent sulphuric acid):

(1) There is a gradual drop in potential to a value of approximately -0.450 V. more active than the saturated calomel electrode during the first 30 min. of exposure. The initial change in potential with time is independent of applied load on the specimen.

(2) After the lowest potential has been reached there may be a gradual increase in potential of approximately 25 mV. or very little change at all. Short breaks in the potential-time curve may occur. These are seen as very rapid rises in potential to a more noble value and then return to 'normal'. The same result is obtained if the surface of the specimen is scratched.

(3) When the specimen fails, there is a sudden rise to a more noble potential.

(4) Cathodic polarization hastens time to failure. Anodic polarization prevents failure but causes pitting and etching attack.

We have a tentative explanation to offer for the observed potential changes. The reason that we qualify our explanation as 'tentative' is that we have additional work in progress to test our theory.

During the initial change in potential to a more active value, dissolution of metal proceeds fairly rapidly. The cathodic process is predominantly the reduction of selenous acid to selenium metal, which appears to be catalysed by the metal surface and deposits there. After the surface is covered by selenium, the potential remains steady or gradually becomes more noble, depending on the adhesion and porosity of the selenium layer. During this interval, if one scratches the surface and breaks the selenium layer exposing bare metal, a repetition of the deposition process occurs at this spot. This is reflected in a sudden rise in the potential and subsequent gradual return. We assume that hydrogen charging becomes the predominant cathodic process after the surface of the specimen is covered by selenium. As one increases the cathodic polarization, the time to failure after the selenium deposition process occurs is greatly decreased. The actual failure of the specimen is mechanical, that is, by hydrogen embrittlement. The reason for the sudden rise in potential is the sudden exposure of bare metal to the corrosive environment.

Another interesting environment is 5 per cent acetic acid with 0.1 per cent ammonium sulphide. The two 12 per cent chromium steels also crack in this environment by hydrogen embrittlement, but there is a major difference in the electrochemical behaviour. The steels still show a gradual potential drop in the more active direction, initially, reaching a value of about -0.520 V. more active than the saturated calomel electrode when cracking occurs. This time, however, there is no apparent change in potential when the specimen fractures or the surface is scratched. We believe the explanation here is that there is no competing cathodic process with hydrogen reduction and no insulating film on the metal surface; the mechanical breaking of the metal, therefore, will not cause a potential change.

These results confirm our opinion that the potential-time curve can be an effective tool in investigations into the cause of cracking of metals even when hydrogen embrittlement is suspected.

We wish to thank the Carpenter Steel Co. for the privilege of publishing this work and Dr. D. van Rooyen for his helpful information on stress corrosion cracking.

Random Slip Model of Fatigue and Coffin's Law

COFFIN¹ has shown that for a number of metals and alloys the relation between n the number of cycles to fracture and ϵ the plastic strain in each cycle is of the simple form:

$$n^{1/2} \epsilon = \text{constant} \quad (1)$$

This equation can be interpreted in a simple way on the model I have proposed². According to this model the surface of the metal is roughened by a more or less random distribution of slip steps. Thus hills and valleys are formed on the surface, and subsequent slip tends to be concentrated in the valleys, roughly in proportion to their depths. The depth of each valley increases or decreases during fatigue in a step-wise manner analogous to a random walk. If $f(z, t)$ is the fraction of valleys (of width w) with depth between z and $z + dz$ after t cycles of fatigue, then $f(z, t)$ obeys a diffusion equation:

$$\frac{df}{dt} = D \frac{d^2 f}{dz^2} \quad (2)$$

The diffusion coefficient D is given by the expression $kbw\epsilon$, where b is the slip vector and k is a geometrical factor of the order of unity.

The enhanced concentration of slip in the deeper valleys is taken into account by letting D be a function

of z . As a rough approximation we suppose that D increases linearly with z and put :

$$D = kbw\varepsilon (1 + \beta z/w)$$

where β is a constant of the order of unity.

The solutions of equation (1) with D a linear function of z have been given by Kepinski³. For large z they behave like $F \exp -z/\alpha$, where α is the rate of increase of D with z , and F is a slowly varying function of z and t . In our case $\alpha = kb\beta\varepsilon$. For small values of t the exponential factor is very small, and no valleys attain any considerable depth. If Z is some large depth then a few valleys attain the depth Z after a number of cycles of the order $Z/15\alpha$. Thus if we take Z to be the depth at which a valley becomes an incipient crack the life-time of the specimen will be given by :

$$n = Z/15\alpha = Z/15 kb\beta\varepsilon \quad (3)$$

We now have to consider how this will change when ε is varied. We may anticipate that the value of Z will depend on the stress-level at which the specimen is fatigued, and thus on the value of ε . On the simple assumption that the plastic strain in each valley is linearly dependent on the depth z , we are led to suggest that the critical depth Z is given by an equation of the form :

$$\varepsilon Z/w = \varepsilon_c$$

where ε_c is a critical value of the plastic strain in a notch which leads to fracture. Combining this value of Z with equation (3) we obtain :

$$n\varepsilon^2 = w\varepsilon_c/15 kb\beta \quad (4)$$

which is equivalent to Coffin's equation.

From this derivation it might appear that this relation is a consequence of the simple linear dependence of D and ε on z . However, the calculation can be carried through for more general forms of dependence of D and ε and a relation of the form (4) is still obtained.

We may derive a value for ε_c from a comparison of equations (4) and (1). The experimental value of the constant in (1) is near unity, and we may insert the values of b and w which were used in the previous note², $w = 10^{-4}$ cm., $b = 5 \times 10^{-7}$ cm. The value of ε_c so obtained is $15 b/w$ or 7.5×10^{-4} . This is of course an extremely rough estimate; but it appears to be a likely order of magnitude for a local plastic strain sufficient to propagate a crack.

One remarkable feature of Coffin's equation is that it is still valid for $n = \frac{1}{2}$, that is, the real strain in fracture by uni-directional strain obeys the same relation. This suggests that the formation of small notches by slip may be relevant in simple ductile fracture as well as in fatigue.

RADIATION CHEMISTRY

Formation of Activated Hydrogen Peroxide by Irradiation of Water with α -Rays

WHEN water is exposed to ionizing radiations the radicals H and OH are produced and these can combine either with each other to give the molecular products H_2 and H_2O_2 , or with solutes¹. In regions of high energy loss (such as α -particle tracks) the local concentration of radicals is sufficiently high for combination between them to occur sooner than reaction with the solute. Consequently, while the chemical effects of X-rays on aqueous solutions are brought about chiefly by radical reactions, those of α -rays are chiefly by molecular reactions. However, in α -irradiations there are δ -rays associated with the α -particle tracks and these always introduce a small fraction of relatively sparsely ionizing radiation which prevents any absolute distinction being made between the effects of X- and α -irradiations.

While studying the effect of ionizing radiations on solutions of proteins, we noticed that polonium α -rays gave rise to changes which were qualitatively different from those brought about by X-rays², but which could not be obtained by treatment with hydrogen peroxide even when this was added to a final concentration of 0.6 M, a thousand times greater than that produced by the α -rays in the water. To elucidate this phenomenon we have compared the effects of X- and α -radiations on solutions of certain amino-acids. With tryptophan in particular, there is clear evidence that an oxidizing agent of reactivity greater than that of normal hydrogen peroxide is formed by the α -rays.

The α -ray source was 100 mc. of polonium-210, deposited on a gold-foil disk, and mounted so that it could be screwed down over an open vessel containing the solution. The whole arrangement was within a container filled with nitrogen. Nitrogen was bubbled through the solution for 30 min. before irradiation and blown over it during irradiation, while the solution was being stirred with a glass-covered rotating magnet. The source of X-rays was a Westinghouse deep-therapy set, run at 220 kV. with no filter. Dose-rates were measured with ferrous sulphate solutions held in the same position as the experimental solutions. The α -radiation was delivered at the rate of 20,000–45,000 rads/hr. ($G = 5.6$) and the X-radiation at 6,640 rads/min. ($G = 15.6$). The tryptophan, from a commercial sample of high purity, was used at a concentration of 2×10^{-4} M in water redistilled in an all-glass apparatus.

Changes in the ultra-violet absorption spectra (differences in extinction coefficient between the irradiated and unirradiated solutions) produced by X- and α -rays are shown in Fig. 1. The loss of absorption at 280 m μ is in both cases connected with loss of the tryptophan chromophore (the indole ring), but the products of the two radiations are evidently different. Hydrogen peroxide at a final concentration of 8×10^{-3} M for 3 days produced no detectable changes. We have confirmed the spectral changes produced by treating tryptophan with ozone³, and find that these closely match the changes produced by α -irradiation. However, the conditions of our experiments preclude the formation of ozone, and even if the irradiations had been carried out in an atmosphere of pure oxygen the yield of ozone would need to be unreasonably large ($G > 50$) if it were to

Fig. 1. Differential absorption spectra (difference between extinctions of irradiated and unirradiated samples) for $2 \times 10^{-4} M$ tryptophan following X-irradiation (86,400 rads) and α -irradiation (59,000 rads). Both irradiations were under nitrogen. ---, α -irradiation; —, X-irradiation.

produce the observed effects. Treatment of the tryptophan with chemically produced OH radicals (from hydrogen peroxide and ferrous sulphate) caused changes in the absorption spectrum which, as expected, closely matched those caused by X-irradiation.

A direct measurement of the indole ring concentration, by the method of Spies and Chambers⁴, showed (Fig. 2a) that the concentration fell more rapidly on α -irradiation (with an initial yield per 100 eV. of $G_{\text{indole}}^{\alpha} = 1.8$) than on X-irradiation ($G_{\text{indole}}^X = 0.92$). However, estimation with Nessler's reagent of the amount of ammonia released (by deamination of the tryptophan) showed (Fig. 2b) that in this respect the radiations were equally efficient ($G_{\text{NH}_3}^{\alpha} = 1.8$). Addition to the solution of 0.1 per cent ribonuclease, a protein containing no tryptophan, protected tryptophan against the radiations; but, whereas in the α -irradiated solution the effective dose to the tryptophan moiety was reduced to about 70 per cent of the dose given to the whole solution, in the X-irradiated solution, the effective dose to the tryptophan was reduced to 35 per cent. These experiments indicate that the molecular product formed in water by α -rays is more reactive and more selective than the radicals produced by the X-rays. Ribonuclease can act as an efficient scavenger for OH radicals, which react readily with all the amino-acids constituting the protein, but it does not compete so effectively for the α -radiation products.

The results show that α -irradiation of water yields a highly oxidizing product which reacts with particular readiness with the indole ring of tryptophan, as

Fig. 2. Analysis of irradiated solutions of $2 \times 10^{-4} M$ tryptophan after various doses of X- and α -irradiation. O, α -irradiated; ●, X-irradiated. a, indole ring concentration; b, ammonia concentration.

does ozone³. However, direct experiment shows that hydrogen peroxide has insufficient reactivity, and the experimental conditions rule out ozone as the product in question. Furthermore, the yields are too high for the product to be the radical HO_2 ($G_{\text{HO}_2}^{\alpha} = 0.15$, ref. 1). We suggest that the product is hydrogen peroxide formed, by the combination of two OH radicals, either in an excited state, or, less probably, in a reactive isomeric form. Since it reacts with a substrate at a concentration of $10^{-4} M$ the life-time of this intermediate must be at least 10^{-8} sec. This eliminates the possibility that a singlet state is involved. But although we have not been able to find any work establishing a triplet state of hydrogen peroxide, the existence of this state is probable on general grounds.

The formation by α -rays of activated hydrogen peroxide as an intermediate of relatively long life-time would create a situation in which α -rays could be more effective than X-rays. A molecule, such as a protein containing tryptophan, would be particularly susceptible to attack in a complex mixture, such as exists in a cell, where the OH radicals formed by X-rays would be used up to a greater extent in reaction with the other substances present. The formation of an activated form of hydrogen peroxide could in this way be one of the causes making the biological efficiency of densely ionizing radiations (for example, α -rays) greater than that of sparsely ionizing radiations (for example, X-rays) though other factors are certain to be involved⁴.

Simultaneous Determination of Scandium and Dysprosium by Neutron Activation followed by γ -Ray Spectrometry

A NEUTRON activation analysis method has been devised for the non-destructive, simultaneous determination of scandium and dysprosium.

It is known that when natural scandium and dysprosium are irradiated with neutrons, scandium-46m (19.5 sec.) and dysprosium-166m (1.25 min.) are formed, respectively. The method of analysis by the use of these nuclides has never been described in the literature examined.

In the present work, the sample (3–80 mgm.) is placed in the nuclear reactor JRR-1 for 30 sec. to be irradiated with neutrons at a flux of 4×10^{10} neutrons/cm.²/sec. (when operated at 5-kW. level), cooled for 10 sec., counted for 30 sec., again cooled for 30 sec. and counted for 30 sec. The counting apparatus used is a 256-channel pulse height analyser to which a 2-in. thick, well-type sodium iodide crystal is attached. In the first counting 128 channels in the analyser are used, and in the second counting the rest used. In the resultant γ -spectrum the height of photopeak due to 0.142-MeV. γ -ray of scandium-46m

and that due to 0.108-MeV. γ -ray of dysprosium-165m are measured, respectively.

The relations between photopeak height and the amount of scandium or dysprosium have been obtained by use of standards.

Table 1. EXAMPLES OF THE COEFFICIENT OF VARIATION AND THE CORRESPONDING SIZE OF PHOTOPEAK

Sample	Coefficient of variation of single analyses (per cent)	Average photopeak height (counts per channel)	Average area of photopeak (counts)
Scandium, 3.07 μ gm.	3.8 ^a 2.1 ^b	1.88×10^3 4.56×10^3	4.3×10^4 7.4×10^4
Dysprosium, 1.62 μ gm.	9.5 ^a	2.60×10^3	4.7×10^4

a. Obtained from the first counting; b, obtained from the second counting.

The examples of the coefficient of variation of single analyses have been obtained by use of five scandium samples, each of which includes 3.07 μ gm. of scandium, and of four dysprosium samples, each of which includes 1.62 μ gm. of dysprosium. The coefficients estimated are shown in Table 1 with the related data.

Results of analyses are shown in Tables 2 and 3.

Table 2. RESULTS OF ANALYSES FOR SYNTHETIC SAMPLES

Sample	Scandium added (μ gm.)	Dysprosium added (μ gm.)	Scandium found* (μ gm.)	Dysprosium found (μ gm.)	
				(a)	(b)
A	0.98	1.62	0.98	1.62	1.77
B	0.98	1.62	0.97	1.59	1.53
C	0.98	1.62	0.92	1.53	1.34

a. Obtained from the first counting; b, obtained from the second counting.

Table 3. RESULTS OF ANALYSES

Sample	Amount of sample (mgm.)	Scandium found (p.p.m.)	Dysprosium found (p.p.m.)
A (Soil)	49.6	19	<3
B (Monazite sand)	3.26	$< 5 \times 10^1$	6.7×10^3
C (Orthite, Korea)	3.55	<10	8.1×10^1

CHEMISTRY

Nature of Fluids in the Hypercritical Region

In the opinion of Andrews¹ the question of the appropriate nomenclature to be applied to a fluid at temperatures and pressures above the critical point "does not admit . . . of a positive answer. . . . Carbonic acid at 35.5°, and under 108 atmospheres pressure, stands nearly midway between the gas and the liquid; and we have no valid grounds for assigning it to the one form of matter any more than to the other". The absence of any sharp visible transition

when a substance is taken from the gas state below the critical temperature to the liquid state, also below the critical temperature, by a route which does not enter the two-phase region of the p, v diagram (that is, cross the two-phase line on the T, p diagram), gave rise to the concept of the 'continuity of gaseous and liquid states'; and this has, perhaps, discouraged inquiry into the structural changes which must occur on passing from a dilute gas to liquid. Suggestions concerning the distinction between gaseous and liquid states of hypercritical fluids were made by Thiessen² in 1897, and later by Eucken³ and by Plank⁴. In recent years, interest in this subject has revived, and several suggestions have been made⁵⁻⁸ that the hypercritical region of the T, p diagram should be divided into areas corresponding to 'gas-like' and 'liquid-like' states of matter by what Bernal⁹ proposes should be called the 'hypercritical line'. The present communication discusses the criteria which have been suggested for making this subdivision.

Smith⁵ has directed attention to the fact that whereas, below the critical temperature, the coefficient of thermal expansion of a substance at constant pressure when plotted against temperature goes to infinity at the boiling point, above the critical temperature it has a maximum. Since real gases are usually characterized by $\partial^2 v / \partial T^2 < 0$ and liquids by $\partial^2 v / \partial T^2 > 0$, this maximum may be regarded as separating gas-like and liquid-like states of the hypercritical fluid. It is found empirically that this maximum occurs at roughly $v_{\max} \approx v_c$, although $v_{\max}$ tends to fall with increasing pressure⁷. In a recent lecture⁶, Bernal suggests that since a sharp maximum is observed when C_p is plotted against temperature at constant pressure^{8,9}, and since such maxima in general reveal the existence of higher-order phase transitions, the locus of this maximum in T, p co-ordinates should be called the hypercritical line separating 'incoherent' from 'coherent' states. Bernal suggests, on geometrical grounds, that this transition should occur at a volume slightly greater than three times the close-packed volume of the molecules. Kaganer⁷ has discussed various ways of dividing up the hypercritical region, and has shown by analysis of the available data that the two methods described above lead to different boundary lines, although they are both smooth prolongations of the saturated vapour pressure curve. He appears to favour the locus of $(\partial C_p / \partial T)_p = 0$ as the most appropriate boundary between liquid and gaseous states, on the grounds that it is the "most natural continuation" of the vapour pressure curve. A similar view is expressed by Jones and Walker⁸.

The close connexion between the criteria suggested by Smith and by Bernal is revealed by the thermodynamic equation $(\partial^2 v / \partial T^2)_p = -(1/T)(\partial C_p / \partial p)_T$, which shows that the locus of maxima in $(\partial v / \partial T)_p$ as a function of T will follow the same path on the T, p diagram as the locus of maxima in C_p as a function of p . This relationship is best illustrated by a three-dimensional model (Fig. 1) in which C_p for argon is shown as a function of T and p . Smith's criterion corresponds to choosing the locus of maxima of the plane sections of the model at constant T (line i), whereas Bernal's is the locus of maxima of plane sections at constant p (line ii). If, however, we choose to employ C_p as the thermodynamic function in terms of which we wish to distinguish the two forms of hypercritical fluid, then the line of the ridge

Fig. 1. C_p for argon as a function of temperature and pressure above the critical point. Data are from refs. 8 and 9.
Line (i): locus of $(\partial C_p / \partial T)_p = 0$
Line (ii): locus of $(\partial C_p / \partial p)_T = 0$

or watershed in the three-dimensional model has a strong claim to be used to define the hypercritical line in the T, p plane. It turns out, however, that although the watershed lies between (i) and (ii), there is no general mathematical criterion which identifies its position uniquely; and, even when the watershed can be defined, its locus on the T, p plane depends on the relative scales employed for T and p . (We are indebted to Dr. T. H. K. Barron for investigating the mathematical definition of the watershed and for pointing out that its locus cannot be defined generally.)

It seems, therefore, that a unique definition of the hypercritical line should not be attempted, but that the physical characteristics of the transition are better described by talking of a 'hypercritical transition region' commencing as a smooth extrapolation of the saturated vapour pressure curve at the critical point, but fanning out at higher temperatures and pressures, and having as its most intense regions the area between the lines defined by $(\partial^2 v / \partial T^2)_p = 0$ (or $(\partial C_p / \partial p)_T = 0$) and $(\partial C_p / \partial T)_p = 0$. The transition is very intense near the critical point so that, for some distance above it, the two lines are barely distinguishable.

It is perhaps also worth noting that, whereas Bernal has invoked a geometrical model to predict

that the transition region should correspond to volumes approximately three times the close-packed volume, an essentially similar conclusion follows directly from the van der Waals' equation, for which $(\partial^2 v / \partial T^2)_p = 0$ when $v_{\max} = 3b = v_c$. It is not clear to us why this result should follow from the van der Waals' model, and it is probably a fortuitous mathematical result; nevertheless, it seems empirically to provide a reasonable approximation to the position of the hypercritical transition region.

Effect of Corona Discharges on Polyethylene

It is known that organic insulation materials deteriorate when subjected to corona discharges. Although many workers have studied the breakdown of insulation materials under the influence of corona, particularly for the purpose of obtaining standardized testing procedures, few have been concerned with the fundamental physical and chemical processes involved.

In the present work *n*-eicosane was used as a model compound for polyethylene. The paraffin was subjected to corona discharges in air, oxygen and carbon dioxide. The experiments were carried out in a cell consisting of two superimposed glass plates spaced 3–5 mm., the outer surfaces of which were made conducting. The paraffin was cast as a thin layer on one of the inner surfaces. The voltage source was a 20-kV. r.m.s. 50 c./sec. transformer.

After exposure to corona discharges for 25–50 hr., the paraffin, which was now partly oxidized, was treated with lithium aluminium hydride in tetrahydrofuran, after which the resulting alcohols were separated by gas chromatography on an 'Apiezon' grease column at 210°C. The chromatogram is shown in Fig. 1.

As will be seen from Fig. 1, only the *n*-mono-alcohols are present. It will further be seen that the

Fig. 1. Gas chromatogram of *n*-mono-alcohols with carbon numbers 8–19 derived from oxidation products of *n*-eicosane. The shaded peaks are *n*-eicosane and its impurities

amount of *n*-heptadecanol ($C_{17}H_{35}OH$) is without comparison the largest. It must therefore be concluded that the discharges cause a scission of a C—C bond, and that the bond between the third and fourth carbon atom is most likely to be attacked.

From mass spectrometer work¹ it is known that this is exactly what happens in the mass spectrometer, where the molecule is ionized after which a charged fragment splits off. The similarity of the fragmentation pattern strongly suggests that the same mechanism is operative also under the influence of corona discharges.

When an alternating voltage is applied to the cell, a discharge will pass when the potential between the two surfaces exceeds the breakdown voltage of the air-gap. In air the breakdown gradient at 1 atm. is 30 kV./cm. and the calculated mean energy of electrons 3.2 eV., whereas the ionization potential for most *n*-paraffins is 10–11 eV. (R. F. Grossman and W. A. Beasley² have suggested a mechanism for the breakdown of polyethylene by corona discharges, based on the assumption of the presence of 28 keV. electrons, which in my opinion is incorrect.)

Assuming a Maxwellian distribution of the energy of the electrons around the mean of 3.2 eV. it can be calculated that 4.2 per cent of them possess energies of 11 eV. or more. As only a minute fraction of the energy input to the cell is involved in chemical transformations of the paraffin, the number of electrons possessing this energy is sufficient to explain an ionization mechanism for the fracture of the molecules.

By varying the experimental conditions, further evidence was furnished in favour of this mechanism, as the extent of bond scission was found to be proportional to the number of electrons that collide with the paraffin surface.

Polyethylene film was then exposed to corona discharges in the same cell. After 25–50 hr. treatment the film was treated with lithium aluminium hydride in tetrahydrofuran. The soluble material was now expected to be diols and was difficult to separate by

gas chromatography. Successful separation was accomplished after converting the diols into their trimethylsilyl ethers by treatment with trimethylchlorosilane in pyridine.

The chromatogram is shown in Fig. 2.

The presence of large amounts of ethylene glycol was not unexpected as crystals of oxalic acid were found on the surface of the film in most experiments. Oxalic acid was also found and characterized by other investigators^{2,3}.

The suggested ionization mechanism applied to polyethylene leads to the following reaction scheme.

When polyethylene is subjected to corona discharges in an oxygen-containing atmosphere, molecules are ionized and a positive ion splits off the molecule end, leaving a free radical which combines with oxygen to an alkoxy radical. This radical is again ionized, splitting off preferably a two-carbon ion, and this process is repeated along the chain. The radical ion which is split off the chain is further oxidized to the diol, the diacid and to carbon dioxide and water, which were also detected as reaction products. Instead of starting at the molecule end only, it can also be assumed that chain end radicals are formed by random scission of the polyethylene chain, after which the process continues as described.

Further work is being carried out and will be reported in more detail elsewhere.

This work was made possible by a grant from N.T.N.F., Royal Norwegian Council for Scientific and Industrial Research. I am also indebted to the University of Glasgow, where this work was carried out, and to Dr. N. Grassie and Dr. G. Eglinton of that University for helpful suggestions.

An Ultra-sensitive Ionization Detector for Permanent Gas Analysis

THE development of a high-sensitivity detector responsive to all elements or compounds in the chromatographic analysis of gaseous mixtures is of importance in the determination of substances present in micro amounts.

A radioactive ionization-type detector similar to the argon detector described by Lovelock¹ was used with helium carrier gas. The metastable helium atoms (19.8 eV.) formed are capable of ionizing, with the exception of neon, all elements and compounds. This means that the technique may be used in the chromatographic analysis of permanent gases where the ionization potentials range from 12 to 16 eV.

Using a molecular sieve 5.4 column of 4 mm. diameter and 30 cm. long, it is possible to determine less than 0.001 μ l. of hydrogen, argon, oxygen, nitrogen, methane and carbon monoxide in less than 2 min. Up to 1 μ l. of gas can be determined before the detector is saturated. The column is operated at room temperature, except when oxygen-argon mixtures are analysed, when cooling to $-80^{\circ}C$. is re-

quired. The limit of detection is approximately 10^{-12} mole of component per ml. of carrier gas.

It is essential to purify the helium carrier gas from all substances other than neon, otherwise too high a background current occurs and the system becomes saturated. It is difficult at this stage to state the permissible impurity level. The ratio of ionization currents for 1 v.p.m. added impurity (nitrogen, oxygen, methane, argon) against the 'pure' helium is 1.05. This is better than the value obtained by Jesse and Sadauskis² of 1.003.

The helium purification system used is a combination of physical and chemical methods, comprising molecular sieve at 20° and -196° C., titanium at 1,000° C. and 'Hopcalite' at 400° C.

A detailed report on the application of this technique to the analysis of permanent gases is to be published.

The electronic equipment for this work was loaned by W. G. Pye, Ltd.

Proton Magnetic Resonance of the Water Phase of Gelatin Gels

RESULTS have recently been reported concerning the proton magnetic resonance line-width of the water phase of starch gels¹. I have examined the solvent line-width of gelatin gels at 16.7 Mc/sec. in a field of 3,910 gauss with the spectrometer now in use at this laboratory. The samples were contained in soda glass tubes of 1.2 mm. inside diameter. Sample spinning at about 1,200 r.p.m. was employed. The instrumental resolution was 0.12 p.p.m. The measurements were carried out at +20° C. The gels were made by solution at 85–90° C. of commercial gelatin in distilled water. The most concentrated gel (0.2 gm. gelatin per ml. water) was also examined with various concentrations of sodium chloride.

The line-width as a function of gelatin concentration is given in Fig. 1 (upper curve). The line-width increases rapidly up to about 6 c/s. at 0.05 gm./ml. At higher concentrations of gelatin the increase in line-width was small. On addition of sodium chloride, the line-width decreased considerably, but did not reach the value for water. As suggested in the article on starch gels¹, this upper limit of line-width of the aqueous phase may be due to the molecular mobility of macro-molecules. Approximate measurements of T_2 by the wobble regrowth method² indicated that T_2 decreased from about 1.5 sec. for distilled water (in equilibrium with air oxygen) to about 0.05 sec. for the most concentrated gel. Approximate measurements were also made on T_1 by the progressive saturation method³. T_1 decreased from about 2 sec. in distilled water to about 0.15 sec. in the most concentrated gel (0.2 gm./ml.).

Work on different types of biological gels is being continued, and the proton resonance of organic macro-molecules is being investigated on gels in heavy water (D_2O).

Fig. 1. Proton magnetic resonance line-widths of gelatin gels. (a) Line-width as a function of gelatin concentration in distilled water. (b) Line-width of a gelatin gel containing 0.2 gm. gelatin/ml. water as a function of concentration of sodium chloride in the gel.

BIOCHEMISTRY

Analysis of Human Leucocyte Deoxyribonucleohistone by Immuno-electrophoresis on Cellulose Acetate

THE internal composition of the nucleus is still unrevealed to a large extent despite many recent advances. The work described here constitutes a new approach to the problem made possible by a combination of histochemistry and immunoelectrophoresis on cellulose acetate membranes. Kohn¹ first introduced cellulose acetate as a supporting membrane for zone electrophoresis, and Consden and Kohn² showed that this material was elegantly suited to the entire process of immunoelectrophoresis. In this laboratory the techniques were found to be easily reproducible³ and are now being used to study the human leukaemic leucocyte, with particular reference to the nucleus.

Fig. 1. Ultra-violet absorption studies of an extract of leukemic leucocytes. Curve *A* is the spectrum of the whole, fresh extract; curve *B* is the spectrum of the material remaining in the sac after overnight dialysis against copious amounts of 0.1 *M* glycine; curve *C* is the spectrum of that portion of the extract which remains soluble after dialysis against 0.15 *M* sodium chloride; curve *D* is the spectrum of the material which is insoluble in 0.15 *M* sodium chloride after it has been re-dissolved in 0.1 *M* glycine. All samples were studied at a dilution of 1:40

In a typical experiment, leucocytes which have been obtained by venepuncture from patients with leukemia are separated from the erythrocytes after accelerating the sedimentation of the latter by the addition of 'Dextran'. Serum proteins are removed by washing the leucocytes three times with 0.1 *M* sodium chloride-0.1 *M* sodium citrate alternating with periods of centrifugation for 1 min. at about 1,500 r.p.m. Two more washes with 0.05 *M* sodium citrate help leach soluble components from the cytoplasm of the now presumably non-viable cells and promote the ultimate dissolution of the nucleus⁴. Treatment with 0.1 *M* glycine then lyses the cells and puts the entire nucleus into solution as shown by phase microscopy. (This method of extracting deoxyribonucleoprotein was suggested by Dr. Daniel Mazia; further discussion of its applications will appear elsewhere.) After extraction has continued overnight, the preparation is freed of sediment by centrifugation at 20,000 r.p.m. for 30 min. All steps are performed at 4°C. and all solutions contain 0.001 *M* ethylenediamine tetraacetate as a further precaution against the action of the enzyme deoxyribonuclease.

The extracts are virtually colourless, slightly opalescent, and not viscous despite the presence of 0.5-1.5 mgm. per ml. of deoxyribonucleic acid as measured by the Dische diphenylamine reaction. About five to eight times as much protein is present

on a weight basis as measured by the Biuret reaction calibrated with crystalline bovine albumin. Typical ultra-violet absorption studies of an extract of leucocytes from a patient (Dal.) with acute lymphocytic leukaemia are shown in Fig. 1. Curve *A* shows that the fresh extract has a peak absorption at 260 mμ and a shoulder at 280 mμ; curve *B* shows that the majority of the extract is non-dialysable; curve *C* shows that most of the ultra-violet absorbing material is insoluble in physiological saline; and curve *D* shows that this insoluble material can be redissolved in 0.1 *M* glycine to give an absorption spectrum characteristic of a nucleoprotein. It is apparent that the extracts are extremely rich in a high molecular weight deoxyribonucleic acid and associated proteins.

Electrophoresis was performed on cellulose acetate membranes supported in a micro-electrophoretic apparatus³. Separations were carried out for 90 min. at a constant voltage of 150 V., which gave an average current of 1.5 m.amp., using a barbital buffer pH 8.6 with an ionic strength of 0.075. At the conclusion of the electrophoretic separation the strips were dried and stained for histone by the method of Alfert and Geschwind⁵ and for deoxyribonucleic acid by the Feulgen technique.

Fig. 2 shows the electrophoretic separation of an extract of cells from a patient (Peg.) with chronic granulocytic leukemia. Strip *A* has been stained for histone and shows two prominent bands migrating toward the anode, one more rapidly than the other. Strip *B* has been stained for deoxyribonucleic acid and shows only a single band migrating also toward the anode. Strip *C* was divided length-wise into two parts after the electrophoretic separation and then stained, *C1* for histone and *C2* for deoxyribonucleic acid. It is clear that all the deoxyribonucleic acid is associated with the faster-moving histone band. Examination of the original strips shows several bands of protein migrating toward the

Fig. 2. Replicate electrophoretograms of an extract of leukemic leucocytes. Strip *A* has been stained for histone, strip *B* has been stained for deoxyribonucleic acid, strip *C* has been divided length-wise after electrophoretic separation and *C1* stained for histone, *C2* for deoxyribonucleic acid. (The anode is at the left)

Fig. 3. Immunoelectrophoretic analysis of an extract of leukemic leucocytes using homologous antiserum. The narrow guide strip along the bottom has been stained for deoxyribonucleic acid, but the Feulgen-positive material reproduced poorly in the photograph. A line drawing of the experiment has been added for extra clarity.

cathode which stain very faintly with the histone stain, but the significance of these remains to be determined.

Antisera were prepared by emulsifying cell extracts with equal parts of Freund's complete adjuvant and injecting the mixture subcutaneously into a rabbit at weekly intervals for four weeks. Serum was collected after the sixth week and used for immunoelectrophoretic work on the composition of the extracts. The technique was that described by Consden and Kohn² with the following modification. Immediately after the electrophoretic separation a narrow guide-strip was cut from one edge of the membrane so that, by appropriate staining, it might serve to identify the location and nature of the substances present on the larger strip. Antiserum was then applied to the opposite edge of the latter and immuno-diffusion allowed to occur at room temperature for two days, following which the precipitin lines were stained with nigrosine.

In Fig. 3 is depicted a typical immunoelectrophoretic and histochemical analysis of an extract of leucocytes from patient Peg. using an antiserum to the extract prepared as described above. The precipitin line under the letter A was clearly seen to be associated with that portion of the electrophoretic separation which gave a positive stain for deoxyribonucleic acid by the Feulgen reaction, thus indicating the location of the deoxyribonucleic acid-histone complex described in the electrophoretic work mentioned above. Line B and possibly line C may well represent precipitin reactions due to the presence of slower moving histones, but definitive evidence is not yet available. The number of precipitin lines indicates the presence of at least five antigenically distinct components in the extract, none of which reacts with potent serum from a rabbit sensitized to human serum.

It remains to be determined which portion of the deoxyribonucleic acid-histone complex is responsible for the antigenicity demonstrated. Other experiments under way include efforts to determine the total number of basic proteins present, to identify the chemical nature of all the antigenically distinct components, to demonstrate possible organ and species differences, and to compare the patterns of leukemic cells with those of normal cells.

This work was supported by grants from the Public Health Service (C-5060), the Martha and Spencer Love Foundation, and Mrs. Sherley W. Morgan. I am indebted to Dr. Daniel Mazia for frequent consultation on this project, to Mary Morrison for valuable technical assistance, and to Dr. David A. Wood, director of the Cancer Research Institute, for his continued interest and support.

Reduction of Nitroso Group in Heterocyclics

IN search of a better and convenient method for the reduction of the 5-nitroso group of substituted pyrimidines, an intermediate for the synthesis of substituted pteridines, required for the synthesis of antagonist of folic acid, as a possible tumour-inhibiting agent (cf. aminopterin and amethopterin), nickel-aluminium alloy in alkaline solution is found to be a very suitable and convenient reagent. Besides the use of nickel-aluminium alloy as catalyst for hydrogenation of various unsaturated compounds, it has been used most successfully in alkaline medium for the reduction of carbonyl groups to the corresponding hydrocarbons or carbinols¹, for the exchange of halogens by hydrogens², for the reduction of isolated, conjugated or cyclic double bonds³, for the hydrogenolysis of alkoxy or methylene dioxy groups in aromatic compounds⁴, various sulphur compounds⁵ and furan derivatives⁶.

It has been reported earlier that the reduction of the 5-nitroso group of the various substituted pyrimidines can be carried out with sodium hydrosulphite, and the corresponding amino derivatives were isolated as their bisulphite salt⁷⁻⁹. Attempts were made to prepare 2:4:5-triamino-6-hydroxy pyrimidine from the corresponding 5-nitroso derivative by the reduction of the latter with sodium hydrosulphite, both in neutral and alkaline medium; but the yield was found to be unsatisfactory, possibly due to the quality of the hydrosulphite used for this purpose. The present method using nickel-aluminium alloy in alkaline medium, as the reducing agent, was found to be very satisfactory.

2:4-Diamino-6-hydroxy pyrimidine was converted into the corresponding 5-nitroso derivative with sodium nitrite in cold hydrochloric acid, which was isolated as an orange-coloured precipitate. Reduction was carried out in warm (50–55°C.), dilute sodium hydroxide solution by adding powdered nickel-aluminium alloy (50 per cent) in portions with vigorous stirring until the red colour of the nitroso compound was completely bleached. The mixture was immediately cooled and filtered from the unreacted alloy when the smell of ammonia was noticed. The cooled filtrate was acidified with sulphuric acid and kept in the cold overnight, when the sulphate of the 2:4:5-triamino-6-hydroxy pyrimidine was crystallized out in fairly good yield. The base was isolated from the corresponding sulphate with sodium bicarbonate and

crystallizing the precipitated base from water, the compound was identified by its analysis as well as the ultra-violet absorption spectrum.

Using the same procedure, 2:4:6-trihydroxy pyrimidine, 2:4-dihydroxy-6-amino pyrimidine and 2-amino-4:6-dihydroxy pyrimidine were converted into their 5-nitroso derivatives, which in turn were smoothly reduced to the corresponding amino derivatives in very good yield. It was, however, observed that 2:4-dihydroxy-6-methyl pyrimidine and 2-hydroxy-4:6-dimethyl pyrimidine could not be converted into their 5-nitroso derivatives under similar conditions. A steric effect possibly is the reason for this failure.

The details of the work will be published elsewhere in due course.

We thank Dr. Subodh Mitra, director of this Centre, for his advice and constant encouragement during the progress of the work.

Selective Inactivation of the Plasminogen Contaminant in Thrombin

THE contamination of preparations of thrombin and fibrinogen with plasminogen, the precursor of the fibrinolytic enzyme, has always presented great difficulties in the measurement of fibrinolytic activity.

When clots prepared from such 'contaminated' substances are used for the assay of fibrinolytic material having activator activity, the resulting lysis will be due to (a) activity of the added plasmin itself, and (b) activation of the contaminant plasminogen in the clot.

While plasminogen contamination of fibrinogen can be reduced to a minimum by applying Laki's procedure¹ three times, no satisfactory procedure has been available to free thrombin preparations from plasminogen. Milstone's method² and an alcohol-fractionation adopted by us (unpublished) result in yields of less than 1 per cent and are therefore impractical. The procedure described here involving incubation of thrombin with the reducing agent, 2-mercaptoethylamine, and its subsequent removal by dialysis results in loss of potential fibrinolytic activity with no impairment of clotting ability.

The contents of 1 vial of bovine 'Thrombin Topical' (Parke, Davis and Co.) containing 10,000 N.I.H. units are dissolved in 10 ml. of 0.5 M 2-mercaptoethylamine hydrochloride (Calif. Found. for Biochem. Res.) previously adjusted to pH 7.4. After 10-min. incubation at room temperature, the solution is dialysed at 4°C. against 10 litres of 1.5×10^{-4} M imidazole buffer, pH 7.0. After 5 hr. the dialysate

is changed and the dialysis continued for 16 hr. Since the two dialyses amount to a million-fold dilution of the original 2-mercaptoethylamine concentration, any amount remaining in the solution is, for all practical purposes, negligible. At the end of dialysis the bag contents (now at pH 6.3 and slightly turbid) are clarified by adjustment of the pH to 7.4. The preparation is poured into siliconized tubes and kept frozen. Even brief exposure of the thrombin to pH values below 5 or above 9, while in the presence of the reducing agent or after its removal, results in rapid loss of clotting activity.

Testing for clotting activity and for plasminogen contamination was done under the conditions of the fibrinolytic assay as used in our laboratory³. Clotting activity was determined by mixing 0.3 ml. of 0.6 per cent human fibrinogen, 0.1 ml. thrombin and 0.2 ml. of a 0.05 M imidazole buffer at pH 7.2 at 45°C. Tests for changes in clotting activity due to the procedure were carried out by determining the clotting time of the above mixture using thrombin treated, and untreated, with 2-mercaptoethylamine, at several dilutions (Table 1). All dilutions of thrombin were made in imidazole buffer. Treatment with 2-mercaptoethylamine resulted in no impairment of clotting activity. Testing for the plasminogen contamination of thrombin samples was carried out by determination of the lysis-times of clots containing increasing amounts of streptokinase (Lederle-Varidase). Three-tenths of a ml. of 0.6 per cent human fibrinogen was mixed with 0.1 ml. containing 1 N.I.H. unit of thrombin (15 sec. clotting time) and 0.2 ml. of a streptokinase dilution; the clots were incubated at 45°C. and observed for lysis. It is essential to employ a series of streptokinase concentrations since full activation of plasminogen by streptokinase occurs only at an optimal ratio of the two substances: too high concentrations of streptokinase depress plasminogen activation^{4,5}. Streptokinase does not directly activate bovine plasminogen present in the thrombin; however, by interacting with traces of human plasminogen⁶ or 'proactivator'⁷ in the human fibrinogen, streptokinase will form 'activator' which now will convert bovine plasminogen to plasmin. Table 2 shows lysis-times of clots made as described above with (a) untreated bovine thrombin, and (b) thrombin treated with 0.5 M 2-mercaptoethylamine, both thrombins in the 1:70 dilution which gave a 15-sec. clotting time. The results indicate a very high degree of inactivation of the plasminogen present as a contaminant in the thrombin preparation. Samples of human plasmin assayed on clots formed with thrombin purified with alcohol or treated with 2-mercaptoethylamine gave identical results indicating that treatment with the latter did not interfere with the lysis of clots by plasmin.

Occasional reactivation of the plasminogen, presumably by re-oxidation of the disulphide bonds on

storage, was prevented by treatment of the preparation with 0.1 M iodoacetamide after the dialysis has reduced the concentration of mercaptoethylamine to approximately 0.01 M as estimated by the nitroprusside test. The excess iodoacetamide was then dialysed out. This procedure, while it sometimes slightly decreases clotting activity, was found to give increased stability.

Inhibition of plasmin by sulphydryl compounds has been reported^{8,9}. In experiments to be described elsewhere we have found that 2-mercaptoethylamine inactivates not only plasmin but also plasminogen. The inactivating effect of 2-mercaptoethylamine on plasminogen is probably due to its reducing property, rather than to the formation of an unactivable complex, since the effect persists after removal of the reducing agent. The most likely explanation of this effect is the splitting of one or more disulphide bonds essential for the activity of the plasminogen molecule. Structural distortion following reduction of disulphide bonds has been observed for several other proteins¹⁰. Since some of the disulphide bonds of thrombin also were probably reduced, as suggested by the increased pH sensitivity of these preparations, we conclude that the readily reducible disulphide bonds are not critical for the maintenance of the functional structure of the thrombin molecule.

Both treated and untreated thrombin tested at a high concentration (10,000 N.I.H. units per ml.), in the absence of streptokinase, lysed the purified clot in 5 hr. Mercaptoethylamine treatment, therefore, did not interfere with the fibrinolytic activity of thrombin itself^{11,12}.

This work was supported by a grant from Parke, Davis and Co.

Blood Trehalose and Fat-Body Glycogen in the Silkworm, *Bombyx mori*

SINCE the report by Wyatt and Kalf¹ that trehalose is the principal carbohydrate in silkworm blood, attention has been paid to the biosynthetic process of this disaccharide in insects. Treherne² showed that trehalose labelled with carbon-14 is synthesized from labelled glucose, fructose and mannose in the locust, *Schistocerca*, and Candy and Kilby³ demonstrated with this insect that the fat-body participates in the biosynthesis of trehalose, where adenosine triphosphate and uridine diphosphate glucose are required as co-factors for the enzymatic reactions involved. However, there are no publications dealing extensively with the correlation between *in vivo* formation of trehalose and various carbohydrates ingested by insects. As for the biosynthesis of glycogen, such a correlation has been elucidated, to some extent, with the fat body and other tissues of insects⁴.

I have recently determined total blood carbohydrates and fat-body glycogen in the silkworm, *Bombyx mori*. The phenol-sulphuric acid method⁵ was employed for the assay of total carbohydrates and glycogen, which was precipitated in alcohol in the presence of added sodium sulphate after digesting lyophilized fat-body in alkaline solution⁶. The same method was used for assaying trehalose, which was extracted from the trehalose spot developed on the filter paper by means of the solvent: *n*-butanol 4, acetic acid 1, and water 1. Trehalase obtained from silkworm midgut was also successfully used for trehalose determination.

When starved, fat-body glycogen decreased rather quickly, to a 60 per cent level of the original in 6 hr., and to a 15 per cent level in 12 hr. This level was maintained during prolonged starvation until the larva started feeding again. The original glycogen-level of the fat-body was resumed in several hours by feeding. Rather a different figure was obtained with total carbohydrates of the blood, the level of which did not decrease during early starvation period, but began to descend around the time when the amount of fat-body glycogen had reached the minimum level. The decrease was gradual so far as 49 hr. starvation. Food intake at the end of starvation resulted in a rapid increase in blood carbohydrates. The adminis-

Table 1

	Erythritol	—

tration of some carbohydrates to the starved larvae also resulted in an increase in blood trehalose. Thus, the increase in both trehalose and glycogen after carbohydrate administration (20 mgm. per larva) in the form of a solution was determined by the use of larvae which had been starved for 49 hr. The rates of increase were different with different carbohydrates, as shown in Table 1.

The most efficient sugars for the increase in fat-body glycogen were glucose, fructose, sucrose, maltose, cellobiose and sorbitol. Melezitose and raffinose were effective, but not so efficient as glucose. Melibiose, trehalose, lactose and starch were intermediate. Xylose, mannose, galactose, and dextrin occasionally resulted in some increase. No effect was obtained with sorbose, arabinose, ribose, rhamnose, methyl- α -glucoside, methyl- α -mannoside, mannitol, inositol, dulcitol, erythritol, glycogen or inulin.

Glucose was the most efficient also for increase in blood trehalose, and the list of carbohydrates falling into this group includes fructose, sucrose, maltose, cellobiose, melibiose, trehalose, lactose, melezitose, raffinose and sorbitol. Xylose, mannose, galactose, mannitol and starch seemed to be slightly effective, but not consistently. Sorbose administration resulted in an accumulation of sorbose in the blood, instead of an increase in trehalose. A similar result was obtained with arabinose, ribose, rhamnose, methyl- α -glucoside and methyl- α -mannoside. Inositol, dulcitol, erythritol, dextrin, glycogen and inulin were not efficient.

It is apparent from those results that the carbohydrates causing an increase in blood trehalose are generally also effective for that in fat-body glycogen. There is a good agreement in the kinds of carbohydrates between nutritive values⁷ and efficiency of the increase in either trehalose or glycogen. Thus, the method determining the rate of increase in either compound by the use of starved larvae is considered to be useful for the evaluation of nutritive values of carbohydrates.

Further details of this work will be published elsewhere.

Reduced Folic Acid Analogues as Antimetabolites

HYDROGENATION of the folic acid analogues aminopterin (4-aminopteroylglutamic acid) and amethopterin (N¹⁰-methyl-4-aminopteroylglutamic acid) is reported to result in diminished antibacterial activity^{1,2} against *Streptococcus faecalis* R (A.T.C.C. 8043) and *Pediococcus cerevisiae* (A.T.C.C. 8081). In view of the lability of tetrahydrofolic acid it seemed desirable to repeat these experiments taking precautions to avoid destruction of the reduced analogues; hence they were added to the assay medium in a potassium ascorbate solution after autoclaving³. The ascorbate did not greatly affect the growth of either

organism. The media employed were similar to those described^{4,5}.

The hydrogenated analogues were synthesized by the procedure described for the preparation of tetrahydrofolic acid⁶, and each product yielded four atoms of hydrogen per mole on iodine titration. They were dissolved in 1 M potassium phosphate, pH 7.8, in serum bottles filled with hydrogen. All dilutions were carried out with a sterile ascorbate solution (6 mgm./ml., pH 6.0).

As shown in Table 1, the reduced compounds are considerably more inhibitory in every instance than the corresponding unreduced analogue. The inhibitory action of aminopterin and N¹⁰-formylaminopterin for *P. cerevisiae* is increased more than 50-fold by hydrogenation. Since reduced folic acid is required for the growth of this organism, the reduced analogues are most likely inhibiting at the tetrahydro level, rather than the reduction of folic acid to tetrahydrofolic acid where the unreduced antifolic compounds are known to act^{7,8}. This suggestion is supported by the fact that with *S. faecalis* R it is more difficult to reverse, with folic acid, the inhibition caused by the reduced analogues than that caused by the unreduced analogues (Table 2). However, the inhibition caused by the reduced compounds is readily reversed by N⁵-formyltetrahydrofolic acid ('Leucovorin') in both organisms excepting the case of the tetrahydroamethopterin inhibition of *S. faecalis* R. It therefore appears as if the enzyme sites involved do not in general bind the tetrahydro analogues tightly.

In the only cell-free enzyme system so far tested, the tetrahydrofolic acid-dependent methionine syn-

^d Ascorbate, as in Table 1.

thesis in *Escherichia coli* extracts⁹ was inhibited 50 per cent by 2.5×10^{-4} M tetrahydroaminopterin or N¹⁰-formyltetrahydroaminopterin, one-third the concentration of the tetrahydrofolic acid present. The unreduced analogues in each case were not inhibitory under the same conditions. In contrast, tetrahydroamethopterin was no more inhibitory than amethopterin. Both compounds yielded only 20 per cent inhibition when equimolar with tetrahydrofolic acid (7.5×10^{-4} M).

These findings suggest that the hydrogenated analogues may be effective therapeutic agents and that they may also be useful in enzyme studies.

I wish to thank Mr. Howard Bakerman, Mrs. Marjorie Romine and Dr. Koula Valassi for help with microbiological assays.

Biotin in the Synthesis of Fatty Acid and Cholesterol by Mammalian Liver

Wakil, Titchener and Gibson¹ have shown that the formation of malonate from acetate and carbon dioxide is an early step in the synthesis of fatty acids in cell-free preparations of pigeon liver. They have also shown that biotin is necessary for this reaction, since it is inhibited by avidin, a specific inhibitor of biotin. By observing the effect of avidin, we have been able to show that, in cell-free preparations of rat liver, biotin is also required for the synthesis from acetate of fatty acids, but is not required for synthesis of cholesterol. It is thus possible to inhibit one biosynthetic pathway without influencing the other.

Homogenates of rat liver were prepared in ice-cold buffer by Bucher and McGarrah's method², and were centrifuged for 20 min. at 2,000*g* to remove nuclei and cell debris, and then for 25 min. at 10,000*g* to remove mitochondria. The supernatant from the second centrifugation, containing the lighter subcellular particles, was transferred to flasks for incubation at 37° C. with air as the gas phase. Each flask received 2.5 ml. of supernatant, 20 μ moles of carbon-14-acetate as precursor of fatty acids and cholesterol, and the additions shown in Table 1. After incubation for 2 hr., the contents of the flasks were hydrolysed with sodium hydroxide. Fatty acids as soaps and cholesterol as digitonide were then isolated from the hydrolysate and assayed for radioactivity by methods previously described³. Table 1 shows the results of a typical experiment. The specific activity of the fatty acids from the flasks containing avidin without biotin was less than 10 per cent of that in the controls. Addition of biotin restored the synthesis of fatty acids almost to the

Table 1. Each flask received 2.5 ml. of liver supernatant fraction and 1.0 ml. of buffer (magnesium chloride, 0.005 M; nicotinamide, 0.03 M; potassium phosphate, 0.1 M, pH 7.4) containing reduced coenzyme I, 1.0 μ mole; coenzyme II, 0.5 μ mole; glutathione, 30 μ moles; adenosine triphosphate, 17.5 μ moles; glucose-6-phosphate, 10 μ moles; potassium bicarbonate, 35 μ moles; potassium malonate, 25 μ moles; coenzyme A, 0.1 μ mole; sodium 1-carbon-14-acetate, 20 μ moles/5 μ c.

Additions	Specific activity (counts/min. at infinite thickness)	
	Fatty acids	Cholesterol
None	24,600	1,860
Biotin, 10 μ gm.	32,500	1,860
Avidin (equivalent to 2 μ gm. biotin)	1,910	1,690
Avidin + biotin	23,300	1,735

control-level. Avidin had no significant effect on the specific activity of the cholesterol isolated at the end of the incubation.

The avidin used in these experiments was kindly supplied by Miss H. Hellig, who prepared it by Woolley and Longworth's method⁴.

PHYSIOLOGY

Effect of Season on the Follicle Stimulating Hormone and Luteinizing Hormone Potency of Sheep Anterior Pituitary Glands

It has been shown in the ewe that the 'total gonadotrophin' hormone content of the pituitary remains about the same during the breeding and during the non-breeding season (Warwick¹). Kamm-lade *et al.*² noticed a rather higher total gonadotrophin hormone-level in the pituitary of the ewe during the non-breeding than during the breeding season. Lamond *et al.*³ found no seasonal variation.

We⁴ have carried out work on the change in levels of follicle stimulating hormone and luteinizing hormone (interstitial-cell stimulating hormone) activity of the pituitary glands of sheep collected at precise stages of the oestrous cycle. In this communication a comparison is made between some of these values and values obtained during the non-breeding season.

The anterior lobes of pituitary glands collected from Welsh mountain ewes kept under controlled conditions have been studied. The seasonal distribution for the collection of these glands is given in Table 1.

Table 1

Reproductive state	Time of year when samples were collected
36 hr.*	7.11.56 - 12.12.56
10 day*	20.11.56 - 14.12.56
Anaestrus	25.7.57 - 28.7.57

* From onset of oestrus.

All glands were excised, the posterior lobe removed, and the anterior lobe trimmed, weighed and frozen over solid carbon dioxide within 15 min. of death. Electrical stunning was not used on any of these animals. The individual glands were then freeze-dried, ground to a fine powder and stored in a desiccator over calcium chloride. The number of glands for each group was 9. For the follicle stimulating hormone determination, aliquots of the samples to be assayed were pooled, homogenized in ice-cold saline and assayed using a slight modification of the Steelman and Pohley⁵ augmentation technique. A $2 \times 2 \times 1$ slope-ratio design with five rats per dose was employed and the assays were analysed by the method of Finney^{6,7}. The follicle stimulating hormone potencies of the pituitaries assayed are expressed in terms of a purified ovine follicle stimulating hormone standard⁸. Estimates of the luteinizing hormone potency of the glands were carried out using the method of Parlow⁹. For these assays pituitary homogenates were extracted with ice-cold saline. A 2×2 or 2×1 design with five rats per dose was employed and the assays were analysed by the method of Gaddum¹⁰. The luteinizing hormone potency of the pituitaries assayed is expressed in terms of a purified ovine luteinizing hormone standard¹¹. The results obtained are given in Table 2. It should be noted that in some cases the fiducial limits are rather wide.

Table 2

Stage of cycle (from onset of oestrus)	Potency (% of standard preparation)	Fiducial limits (95%)	Type of assay
Follicle-stimulating hormone values			
36 hr.	0.071	0.042-0.102	$2 \times 2 + 1$
10 day	0.143	0.111-0.183	$2 \times 2 + 1$
Anoestrus	0.180	0.145-0.228	$2 \times 2 + 1$
Luteinizing hormone values			
36 hr.	0.472	0.301-0.776	2×1
10 day	1.535	0.748-9.040	2×1
Anoestrus	1.051	0.471-6.682	2×2

From the above values it would appear that the follicle stimulating hormone and luteinizing hormone potency of the pituitary gland during the anoestrous state is of a similar order to that found during the breeding season. The value for follicle stimulating hormone is as high as the maximal value found during the pre-ovulatory phase of the cycle while the value for luteinizing hormone is similar to the mean value for the cycle.

During the non-breeding season the ovary is far from inactive in the ewe. The ovaries from the non-breeding ewes in the present work have as many large (4 mm. diam. or greater) follicles as, and a greater number of small (2-3 diam.) follicles than, the ovaries of ewes during the oestrous cycle. The size of the largest follicle in the ovaries of the ewes during the non-breeding season is similar to that for ewes during the breeding season excluding a 20 hr. pre-ovulatory period. No recent corpora lutea were present in the ovaries of the ewes during the non-breeding season, indicating a lack of ovulation during this time. If the maintenance of the large follicles found in ovaries of ewes during the non-breeding season is under gonadotrophin control then a constant or cyclic release of gonadotrophin from the pituitary should occur at this time. There must also be a constant production to maintain the levels of follicle stimulating hormone and luteinizing hormone which we have found in the pituitary. Kammlade *et al.*²

suggested that the lack of ovulation during the breeding season was due to a deficiency of luteinizing hormone in the pituitary. The values reported here for the potency of luteinizing hormone of the pituitaries would indicate that the pituitary of the non-breeding ewe is not devoid of the hormone. The lack of ovulation observed during the non-breeding season may be due to a lack of a sudden substantial release of luteinizing hormone and follicle stimulating hormone from the pituitary such as we⁴ have found to occur during the ovulatory phase of the oestrous cycle, rather than to a lack of these hormones in the gland.

A full account of this investigation is being published elsewhere.

We are indebted to Messrs. Armour Laboratories for the samples of purified follicle stimulating hormone and luteinizing hormone, to Messrs. Parke, Davis for chorionic gonadotrophin and to Messrs. Boots for pregnant mares' serum gonadotrophin.

Uptake of Small Resin Particles (1-5 μ Diameter) by the Alimentary Canal of the Calf

THE intact skin and mucous membranes of the healthy body appear to present an impenetrable barrier to the entrance of particulate material, but yet bacteria are able to enter. How they do so is unknown. The tonsil is thought to be a vulnerable site: *Mycobacterium tuberculosis* has been shown to enter here¹, and even carmine granules dusted on to the tonsils before surgical removal penetrated very rapidly into the connective tissues². The wall of the small intestine is also permeable to bacteria; coliform organisms³, *M. tuberculosis*¹ and *Salmonellae*⁴ have been shown to pass through the apparently intact mucous membrane and spread to the mesenteric lymph nodes, the blood, liver and spleen. More recently, at this Station, we have found that *Mycobacterium johnei* is also capable of rapid and extensive invasion of the body after the administration of an oral dose of culture to calves (Payne, J. M., and Rankin, J. D., unpublished work).

It was decided to see if inert particles would be taken up in the same way as bacteria. Previous experiments of this kind, using inert particles such as carmine⁵, graphite⁶ and polymethyl methacrylate spheres⁷, to imitate bacteria have had limited or no

Fig. 1. Radioactive particles in the wall of the pharynx. H&E stain. ($\times 80$)

Fig. 2. Radioactive particles in cells lining a sinus in a lymph node. H&E stain. ($\times 360$)

success, for even when fed in large amounts they only passed through to a limited extent or not at all. In view of the difficulty of estimating small quantities of these substances, we decided to use radioactive particles, which had the advantages of being easily detected and counted in body tissues.

Radioactive resin particles were prepared by one of us (B. J. M.). A stock suspension of these was made by grinding resin beads in a vibratory ball mill, followed by gravity sedimentation, centrifugation to eliminate large particles and finally filtration, with repeated washing, through a series of sintered glass filters so as to collect particles known to be between 1 and 5μ in diameter. Gold-198 was then adsorbed and reduced on to a sample of the final preparation. By this means a product could be obtained containing 50 mgm. resin particles of size 1– 5μ , firmly labelled with 40 mc. of gold-198, having a total count of 1.7×10^{10} counts/min. The stability of the gold on the particles was checked by re-filtration through a No. 5 sintered glass filter. Only trace amounts of radioactivity came through into the filtrate, indicating firm labelling. This check was important, for in a preliminary experiment some loss of gold from the particles was observed.

Table 1

Lymph nodes	Counts/min./10 gm.	Tissue and fluids	Counts/min./10 gm.
Parotid	763	Tonsil	1,627
Mandibular	941	Pharynx	301
Suprathyroid	189	Lung	700
Mediastinal	2,483	Liver	189
Bronchial	794	Kidney	293
Hepatic	118	Spleen	242
Mesenteric	182	Muscle	56
Ileocaecal	361	Testis	246
Iliac	176	Blood	70
Precurial	1,718	Bile	25
Precaudal	2,052		
Popliteal	1,576		

The dose of particles was mixed with milk and fed to a calf six weeks old which was killed 72 hr. later and a variety of tissue samples removed and their radioactivity estimated in a well-type γ -scintillation counter. All counts were corrected for radioactive decay to the time of dosing. In addition, tissue sections were rapidly prepared by routine histological methods and covered with autoradiographic stripping film so that the precise localization of radioactivity could be determined. The results are shown in Table 1.

Radioactivity was relatively high in the tonsil and certain lymph nodes but low in the blood, muscle and bile. This result is, as would be expected if the particles were absorbed through the tonsil and alimentary canal, followed by distribution in the reticulo-endothelial system of the body. Confirmation of this was obtained by autoradiography, in which the localization of apparently individual particles could be traced in the tissues by the presence of tiny areas of dense blackening in the stripping film. By this means particles could be detected in the wall of the tonsil, pharynx (Fig. 1) and small intestine. Within the body they appeared to be associated with cells of the reticulo-endothelial system, particularly in lymph nodes (Fig. 2) and the spleen.

We conclude from these experiments that small numbers of particles of 1– 5μ diameter can penetrate through the mucous membrane of the tonsil, pharynx and small intestine and be carried throughout the body, in apparently the same manner as bacteria. We suggest that the use of radioactive particles of this kind may prove to be a sensitive method for the study of various problems of infectious disease and possibly also in work on nutrition and nutritional allergy. Further details and results of experiments now in progress will be reported elsewhere.

Influence of Tranquillizing Drugs on Phagocytosis *in vivo*

PHAGOCYTOSIS of invading micro-organisms has long been known to play a major part in the defence of the mammalian organism against infectious disease. In view of the widespread use and potent pharmacological activity of the tranquillizing drugs, it is not surprising that administration of such compounds has occasionally been associated with alterations in normal resistance to infection^{1,2}, and that such altered clinical responses have been linked to changes in the phagocytic activity of the reticulo-endothelial system³.

Vinegar and Berger⁴ have recently reported that, in high doses, chlorpromazine, hydroxyzine and reserpine slowed the clearance of carbon particles from the blood of mice, but did not do so in low doses. Carbon particle clearance was not altered by meprobamate in either high or low doses. On the other hand, at the low dose employed by Vinegar and Berger, Ludány^{5,6} found marked inhibition by chlorpromazine of the phagocytic activity of leucocytes from peripheral blood of dogs and rabbits.

In an effort to approximate more closely natural conditions than either carbon clearance or *in vitro* phagocytosis, an *in vivo* bacterial study was undertaken. Large male Wistar rats in groups of four were injected intraperitoneally with tranquillizing agents suspended in 5 per cent acacia solution. Three doses, 8 hr. apart, were administered to the experimental animals while control animals received 5 per cent acacia solution on the same schedule. All food was withheld during the experiment since it has been reported that phagocytic activity is enhanced by starvation⁷.

Eight hours after the last injection of tranquillizer or acacia solution, each animal received 20 ml. intraperitoneally of broth culture of *Staphylococcus aureus* filtered through sterile glass wool and diluted with sterile saline to give approximately 50 per cent transmittance on a Coleman 'Junior' spectrophotometer. After 3 hr., animals were killed by decapitation and the peritoneal cavity opened. Duplicate slides of the contents were prepared, stained and counted for phagocytic activity by the method of Kuna *et al.*⁷.

Table 1. EFFECT OF PRETREATMENT WITH TRANQUILLIZERS ON THE PHAGOCYTIC ACTIVITY OF RAT LEUCOCYTES

Drug	Dose (mgm./kgm.)	Percentage of cells showing phagocytosis	Mean (per cent $\pm$ S.E.)	Significance of difference from control (<i>t</i> test)
5 per cent acacia (control)	—	32 38 24 31	31 $\pm$ 3	—
Chlorpromazine	25	63 71 86 70	73 $\pm$ 8	$P < 0.01$
Reserpine	1	20 17 27 25	22 $\pm$ 2	$P < 0.05$
Meprobamate	200	40 63 64 30	49 $\pm$ 8	$P > 0.05$
Hydroxyzine	25	30 31 22 36	30 $\pm$ 3	$P > 0.7$

Table 1 shows the effects of the four test agents on phagocytic activity as compared to acacia controls in a single run. It is apparent that pretreatment of rats with tranquillizing drugs resulted in marked alterations in phagocytic activity, with reserpine significantly depressing phagocytosis, chlorpromazine significantly enhancing phagocytosis, and hydroxyzine and meprobamate being largely without effect in this regard.

Analysis of variance⁸ of the data obtained confirms the fact that the variation in phagocytic activity following drug treatment does not represent variation within a single population.

Repetition of the experiment at later dates gave comparable results, and the control values obtained by us are in agreement with reported values for untreated, starved rats⁷.

Influence of the Surface of the Small Intestine on Enzymatic Hydrolysis of Starch by Enzymes

THE classical conception of digestion as being the sum of processes occurring in the chyme under the influence of hydrolytic enzymes fails to explain many important physiological and clinical phenomena.

In previous papers^{1,2} it was shown that cavital (chyme) digestion is probably not the sole or main mechanism underlying the hydrolysis of food. It was suggested that the surface of the intestine presents a living porous reactor (the pores being formed by microvilli), on the surface of which intensive hydrolysis occurs on account of enzymes (self-contained and adsorbed) on the external side of the cellular membrane. (The presence of microvilli was first demonstrated by Granger and Baker³ and later confirmed by many authors.)

The enzymes form a rather strong layer, which possibly has an ultrastructure analogous to what is known about enzymes on the membrane of mitochondria.

This is of great importance and suggests an enzymatic conveyor ensuring continued splitting followed by absorption of the food.

The system of processes occurring on the surface of the intestine we have designated as membrane or contact digestion¹.

Previous experiments have revealed that hydrolysis of larger molecules occurs mainly under the influence of dissolved enzymes while intermediate products are better split on the intestine surface. Thus, membrane digestion seems to be the intermediate link between cavital hydrolysis and absorption. For the latter it is the main source of providing substances for resorption².

The comparison of amylolytic hydrolysis *in vitro* and in the intestine has shown that the considerably greater speed of starch digestion in the organism is due to the operation of membrane hydrolysis and the interaction of the latter with hydrolysis in the chyme. These results were confirmed by model tests *in vitro*. It was established that the addition of a piece of living intestine to a pancreatic amylase solution results in a sharp increase in the speed of starch hydrolysis, which considerably exceeds the sum of the amylolytic activities of the solution and the intestine taken separately. It was further established that not only living intestine but also that first treated with trichloroacetic acid and then washed, that is, an intestine without any enzymatic activity of its own, considerably increases the activity of pancreatic amylase. A special analysis has shown that a certain amount of dissolved enzymes is adsorbed on the surface of the intestine, and thus a system is created in the test tube in which interaction of cavital and membrane hydrolysis occurs^{1,2}.

Judging by the increase of amylase activity following the addition of mucosa treated with trichloroacetic acid, membrane digestion is practically absent in the oesophagus, is only slightly marked in the large intestine and the stomach, and is well marked in the small intestine. Taking into consideration that membrane digestion should be preceded by cavital digestion and the former is closely related with absorption, such a topography will not seem casual.

Yet the question of what groups of animals are characterized by membrane digestion remained uncertain as former investigations were conducted on albino rats only.

The present work presents an investigation of the ability of pieces of mucosa taken from the small intestine of various animals to increase the activity of pancreatic amylase *in vitro*. Pieces of mucosa (1-1.5 sq. cm.) from the upper portions of the small intestine were taken from albino rats, albino mice, rabbits, cats, pigeons and frogs. The pieces were quickly taken from narcotized animals, washed in cooled Ringer's solution and then placed into a 5 per cent solution of trichloroacetic acid. The concluding stage of treatment consisted of continuous and repeated washing in Ringer's solution at the temperature of 2-4° C. (Methods of preparing trichloroacetic acid models are described in greater detail elsewhere¹. The amylolytic activity was determined colorimetrically by the reduction of starch iodine staining Smith-Roy's method, somewhat modified.) The concentrations of the pancreatic crystalline amylase were so selected that the starch hydrolysis was 30-50 per cent in 30 min. at 38° C. and pH 7.2.

Special tests proved the absence of substances activating the amylase in the trichloroacetic acid intestine models.

As shown in Fig. 1, the mucosa of the small intestine of a pigeon, albino mice, rabbit and a cat possesses the ability to increase amylase activity *in vitro*, approximately to the same degree as the well-investigated small intestine mucosa of the rat. I consider

Fig. 1. Influence of pieces of mucosa from the small intestine on starch hydrolysis with amylase in various animals. Increase of activity is shown by the hatched part of the column above the background line. The activity of amylase solution is taken as 100 per cent; the trichloroacetic acid intestine models possess no amylolytic activity of their own

this effect (with the reservations quite natural in such cases) to be a manifestation of membrane activity. The above experiments suggest the assumption that membrane digestion is inherent to all higher animals having various types of food ingestion. It is interesting that the same phenomenon, though to a lesser degree, is caused by the mucosa of the small intestine of the frog in which the typical villi are absent. Yet in Amphibia microvilli have been described which we are inclined to consider the structural basis of membrane digestion. If only this assumption is correct, membrane digestion must occur in the great majority of animal groups, for microvilli have been described even in roundworms⁴.

HÆMATOLOGY

Genetic Aspects of Two Different Minor Hæmoglobin Components found in Cord Blood Samples of Negro Babies

DURING work on the hæmoglobin types in the cord blood of Negro babies 70 samples were investigated by starch-gel electrophoresis¹. The following results were obtained: 52 cases with HbA and HbF; 10 cases with HbA, HbF, and HbS; 3 cases with HbA, HbF and HbC; 3 cases with HbA, HbF, HbS, and a fast-moving component I; 1 case with HbA, HbF, and a fast-moving component II and 1 case with HbA, HbF, HbS, and a fast-moving component II. Using the carboxymethylcellulose chromatographic method^{2,3}, component I was found to be present for 3.2, 1.4 and 2.9 per cent respectively and component II for 5.6 and 6.5 per cent respectively. Work on the isolated fast-moving hæmoglobin fractions (prepared

by CMC chromatography) have shown that the two minor fractions were entirely different in structure⁴⁻⁶. These differences may be summarized as follows: (a) component I was slightly more resistant towards alkali than HbA, while the denaturation-rate of component II was intermediate between those of HbA and of HbF; (b) the ultra-violet spectrum of component I was similar to that of HbA, while the ultra-violet spectrum of component II was of the type found for HbF; (c) 'Amberlite IRC-50' chromatography of the globins prepared from the two haemoglobin fractions at pH 1.9 with a urea gradient from 2 to 8 M revealed the presence of only β -polypeptide chains in component I and only γ -chains in component II; (d) sickle-cell haemoglobin was formed as hybrid from a mixture of component I and normal HbA, and foetal haemoglobin from a mixture of component II and HbA. It seems, therefore, that component I (called 'Augusta I') consisted entirely of the β -chains of HbS, while component II is identical with Bart's haemoglobin in being composed solely of the γ -chains of foetal haemoglobin.

Haemoglobin studies of family members were possible for one family with the 'Augusta I' component and for two families with the Bart's haemoglobin. The haemoglobin samples were studied by starch-gel electrophoresis¹, by CMC chromatography^{2,3} and by an alkali denaturation procedure³. In the 'Augusta I' family, the father and his sister, the mother, seven children (including the new-born baby) were available. In the blood of the new-born child HbA, HbF, 3.2 per cent of 'Augusta I', 0.8 per cent of HbS were demonstrable; the percentage of the fast-moving component being decreased to 2.1 per cent and the amount of HbS increased to 1.9 per cent⁵, in a period of 45 days. Small amounts of an Hb-H-like component were also demonstrable in the cord blood sample. The mother and one of the children were completely normal; no increased percentages of HbF were detectable, while the HbA₂ component was present for 1.9 and 2.1 per cent. The father, his sister and three other children were heterozygous for HbS. Next to this abnormal haemoglobin, however, minute amounts (about 0.1 per cent) of a fast-moving fraction were demonstrable. This fraction possessed electrophoretic properties similar to those of HbH (or β_4A). It seems, therefore, that these family members were also 'heterozygous for the α -chain deficiency', resulting in the formation of very small amounts of HbH. The two other children were heterozygous for the sickle cell haemoglobin; no fast-moving fraction was demonstrable in the haemolysates of their red blood cells. These results indicate that two genetically determined haemoglobin abnormalities were present in this family⁵, both being inherited independently.

In the first family with Bart's haemoglobin, blood samples obtained from the father, the mother, and seven children (including the new-born baby) were available. The amount of Bart's haemoglobin in the blood of the new-born baby (as determined by CMC chromatography) was 5.6 per cent, foetal haemoglobin was present for 60.7 per cent, while a small amount of HbA₂ (0.5 per cent) also was demonstrable. The haemoglobins of both parents and of the six other children showed no abnormalities; the percentages of foetal haemoglobin were less than 1 per cent, while the amounts of HbA₂ ranged between 1.9 and 2.3 per cent.

In the second case, the percentage of Bart's haemoglobin was 6.5 per cent, while next to HbA, HbF (68 per cent), small amounts of HbS (4.7 per cent)

and of HbA₂ (0.2 per cent) were present. Blood samples of both parents were available for study. The haemoglobin of the mother was completely normal (HbF less than 1 per cent, HbA₂: 1.9 per cent), while the father had the sickle-cell trait (HbS: 34.5 per cent, HbA₂: 2.1 per cent, HbF less than 1 per cent). No other abnormalities were demonstrable.

The results of these family studies are of some special genetic interest since in the first family an abnormality in the production of the adult haemoglobin types HbA and HbS is present during foetal and adult life, while in the other two families an abnormal foetal haemoglobin is formed during foetal life without any visible alteration in the pattern of adult haemoglobin. It is likely that all three new-born babies suffered from a 'heterozygous α -chain deficiency', resulting, however, in the formation of entirely different ' α -chain lacking' abnormal haemoglobin types. These findings suggest a qualitative difference in the α -chain deficiency, to be explained by a suppression of the formation of the adult α -chain in members of the first family and of the foetal α -chain in members of the other two families. Therefore my results offer evidence that the production of adult and foetal α -chains is controlled independently by two α -genes, which, however, must be almost identical in fine detail since the α -chains of HbA and of HbF do not show structural differences by the finger-printing technique, or by hybridization⁸⁻¹⁰. The adult α -chain deficiency seems to be more pronounced during foetal life, but is still visible after birth by the production of small amounts of HbH. The 'foetal α -chain deficiency' is confined to the synthesis of foetal haemoglobin; thus, no abnormalities are detectable in adult life.

The possibility exists that a heterozygosity for both adult and foetal α -chain deficiencies is present in one individual and results in the presence of an abnormal adult haemoglobin (as 'Augusta I') and of the abnormal foetal haemoglobin (Bart's haemoglobin) in the same cord-blood sample. Evidence for the existence of this double heterozygosity was obtained by demonstrating two fast-moving minor haemoglobin components in the blood of a new-born baby next to HbA, HbF and small amounts of HbC. The fastest-moving minor fraction was electrophoretically similar to Bart's haemoglobin, while the slowest-moving minor fraction ('Augusta II') was probably composed solely of the abnormal β -chain of HbC. Unfortunately, examination of the haemoglobins of family members was not possible.

These investigations were supported in part by Public Health Service Grant No. H-5168.

The Diego Factor in Japanese

It is already known that the study of blood groups and types and their distribution and heredity are of great significance in anthropology.

Since the Diego blood group was originally reported¹ in 1954 the investigation of this blood group and its incidence in different races of various countries have been reported by several authors. At present, the Diego factor has been found in the blood of South American Indians, and mixed bloods in Venezuela, Brazil, North American Indians, and Chinese and Japanese residents in Canada and Venezuela. No Diego factor was discovered in Caucasians and Negroes; therefore it seems that the Diego factor is an anthropological characteristic of Indians and Mongoloids.

The first investigation of the Diego factor in Japanese in Japan was carried out by Furuhashi, Yokoyama and Kuniyuki² in Tokyo, and they found 2 (2.3 per cent) Diego positive (Di(a+)) bloods in 88 samples. The anti-Diego serum was kindly supplied by Dr. Philip Levine, Ortho Research Foundation, Raritan, New Jersey, for this investigation. The serum showed activity and clear-cut results by indirect Coombs test.

We received another antiserum through the courtesy of Dr. Miguel Layrisse, Banco de Sangre, Caracas, Venezuela, for the second study. This time we used serum to test the blood of people in Tokyo and in Kumamoto located in the southern part of Japan. Tests were made by the indirect Coombs technique and the results were 6 (4.1 per cent) of Di(a+) bloods in 146 random samples in Tokyo and 17 (7.5 per cent) in 227 unrelated people in Kumamoto.

Masaki and Furukawa³ reported the frequency of the Diego factor as 16 (3.2 per cent) in 500 Japanese living in the Gumma area. They used anti-Diego serum obtained from Dr. James F. Mohn, Buffalo University, Buffalo, New York.

The incidence of the Diego factor in Japanese from our investigation is approximately 3-4 per cent in Tokyo and is a little lower than the 8 in 65 cases (12.3 per cent) in Venezuela reported by Layrisse and Arends⁴ and the 6 in 77 cases (7.8 per cent) in Canada reported by Lewis, Ayukawa, Chown and Levine⁵. However, the incidence of the Diego factor was found to be about 7.5 per cent in the southern part of Japan. Moreover, Dr. Paul J. Schmidt (personal communication), Blood Bank, National Institutes of Health, United States, found an incidence of nearly 10 per cent of the Diego factor in samples from Fukuoka located on the same island as Kumamoto. One of us (N. U., personal communication) examined samples in Kumamoto more recently and found 8.7 per cent Diego-positive bloods.

Table 1. FREQUENCY OF DIEGO FACTOR IN JAPANESE

Authors	Tested No.	Diego factor	
		Pos. (%)	Neg. (%)
Layrisse and Arends (1956)	65	8 (12.3)	67 (87.7)
Lewis, Ayukawa, Chown and Levine (1956)	77	6 (7.8)	71 (92.2)
Furuhashi, Yokoyama and Kuniyuki (1957)	88	2 (2.3)	86 (97.7)
Masaki and Furukawa (1959)	500	16 (3.2)	484 (96.8)
Yokoyama, Murakata and Ueno (1960)	146*	6 (4.1)	50 (95.9)
	227†	17 (7.5)	210 (92.5)

* Tested in Tokyo. † Tested in Kumamoto. The number includes 5 (6.7 per cent) Diego positive of 74 random samples previously cited by Layrisse, M., *Amer. J. Phys. Anthropol.*, 16(2), 173 (1958).

From our present results, there appears to be a lower incidence of the Diego factor in northern Japan, with the incidence gradually increasing and reaching the highest incidence in Japanese in the southern part of Japan. This frequency suggests that the Diego factor may be an Asiatic characteristic as are factors for group B, Rh₀, kk and Gm^a.

We are indebted to Dr. P. Levine and Dr. M. Layrisse for the sera used in the testing.

RADIOBIOLOGY

Alkoxyglycerols as Growth-stimulating Substances

In connexion with experiments on irradiated rats, it has been shown that the alkoxyglycerols or their esters prohibit to a certain extent the decrease both of megakaryocytes and of nucleated cells in the bone marrow, a decrease which usually occurs after irradiation¹. When radiomimetic substances (for example, leukeran and myleran) are given to rats, a diminution of the above types of cells is equally observed. This diminution is also partly prevented by alkoxyglycerols.

It has now been found that the alkoxyglycerols have an effect not only on the bone marrow, but they also influence the growth of the rats. In general, normal, non-irradiated rats increase in weight more rapidly than irradiated rats. However, when irradiated rats were prophylactically treated with alkoxyglycerols the increase in weight was higher than for the irradiated control group, which received no treatment. The normal non-irradiated group showed an increase of 1.7 gm. a day per animal, the prophylactically treated group 1.3 gm. and the control group 1.1 gm.

When the alkoxyglycerols were found to promote the growth of rats, it seemed desirable to try their effect on *Lactobacilli*, which have been used as test organisms for many growth-stimulating substances. Twelve strains of *Lactobacilli* were tested. Pure synthetic media were used as substrates. The growth was determined turbidimetrically. The best results were found for *Lactobacillus lactis* (Fig. 1). The cultures were transferred to two sets of tubes, one control set with synthetic substrates and one with substrates to which had been added selachyl alcohol (an unsaturated alkoxyglycerol). A very striking effect is observed at a concentration of 20γ per ml. of alkoxyglycerols, but even at a concentration of 2γ per ml. a clearly observable effect is obtained. (I am indebted to Dr. Lennart Enebo for the performance of these experiments.)

Fig. 1. Effect of selachylalcohol on the growth of *Lactobacillus lactis*. A, Synthetic substrate + 20γ selachylalcohol per ml.; B, synthetic substrate + 2γ selachylalcohol per ml.; C, control, synthetic substrate only.

The observation that alkoxyglycerols stimulate growth is of interest since these substances are found in the blood-forming tissues (cf. ref. 2). From experiments on rats (*loc. cit.*) it was found that the alkoxyglycerols had an effect on both megakaryocytes and nucleated cells (from which derive several types of cells in the peripheral blood). The blood-stimulating factor vitamin B₁₂ has an effect only on the red cells.

Very little is known of the formation of alkoxyglycerols in the body and of their presence in different foods. The effect of alkoxyglycerols in nutrition would be an interesting subject for further investigations.

A more detailed report of these experiments will be published elsewhere.

An Apparent Difference in the Renal Clearance of Calcium-45 and Calcium-40 in Rats

In investigating the comparative excretion of calcium-45 and strontium-89 in rats we have encountered evidence of unexpected variability in the renal clearance of calcium-45 and calcium-40. This finding may be significant in metabolic work employing radiocalcium as a tracer.

Weanling female Sprague-Dawley rats (group I) were injected intraperitoneally with 1.0 ml. of a solution containing carrier-free strontium-89, calcium-45, and 0.05 mgm. of calcium. Using methods previously described¹ urine was collected at the end of 30 min. and 60 min., and analysed for strontium-89, calcium-45 and total calcium. One hour after injection, blood was obtained from each rat by cardiac aspiration, and the concentration of strontium-89 and calcium-45 in the plasma was determined. A comparable group of rats (group II) was denied food for 12 hr. and the experiment repeated. The results are presented in Tables 1 and 2.

Table 1. CONCENTRATION OF STRONTIUM-89 AND CALCIUM-45 IN PLASMA

Group	No. of rats	Percentage of dose/ml.		
		Strontium-89	Calcium-45	Sr-89/Ca-45
I	6	0.50 ± 0.03*	0.49 ± 0.02	1.01 ± 0.02
II	8	0.56 ± 0.02	0.56 ± 0.20	0.99 ± 0.01

* S.E.

Calcium-45 and strontium-89 occurred in slightly higher concentrations in the plasma of group II rats, yet these animals excreted considerably less of each during both collection periods. From the strontium-89/calcium-45 ratios in urine and in plasma it is further apparent that the renal clearance of calcium-45 was decreased more than that of strontium-89. This finding agrees with a previous report from this laboratory¹ which showed a progressive decrease with time in the renal clearance of calcium-45, relative to strontium-89, following the intraperitoneal injection of these isotopes.

Despite the markedly different excretion of labelled calcium, both groups of rats excreted equivalent amounts of total calcium. The reason for this is not apparent. It is unlikely that the short period of food denial would affect the total serum calcium. There is also no reason for believing that the renal clearance-rates of calcium-45 and calcium-40 differ intrinsically. While a slower absorption of the injected calcium-45 could account for its diminished excretion by group II rats, the results of a separate experiment would serve to rule out this possibility. Here it was found that the plasma of similarly starved rats contained a higher percentage of calcium-45 30 min. after injection than did that of non-starved controls, namely, 1.20 per cent and 0.89 per cent respectively. (Corresponding 1-hr. values were

Table 2. URINARY EXCRETION OF STRONTIUM-89, CALCIUM-45 AND CALCIUM

Group	No. of rats	Period (min.)	Percentage of dose excreted			
			Strontium-89	Calcium-45	Sr-89/Ca-45	Calcium excreted (mgm.)
I	6	0-30	3.15 ± 0.60*	0.81 ± 0.26	7.2 ± 2.9	1.09 ± 0.07
II	8	0-30	0.31 ± 0.06	0.02 ± 0.001	13.0 ± 1.6	1.12 ± 0.09
I	6	30-60	1.31 ± 0.36	0.32 ± 0.14	5.4 ± 0.9	0.87 ± 0.05
II	8	30-60	0.17 ± 0.03	0.03 ± 0.008	6.2 ± 0.8	0.84 ± 0.03

* S.E.

0.52 per cent and 0.46 per cent.) An explanation for the disproportionate excretion of calcium-45 and total calcium under these conditions may possibly be found in a different partitioning of the injected label among the body calcium pools.

Uptake of Phosphorus-32 by the Roots of *Lolium perenne*

PREVIOUS work on the ability of various portions of the root to supply the shoot with minerals has been carried out using the seminal roots of cereals grown in nutrient solution when the plants were a few days old. Weibe and Kramer¹ considered that in barley the most active zone of absorption and translocation of minerals was situated some distance behind the tip. The results of Lundegårdh², also working on barley, indicated that most nitrate was translocated from the basal portion of the root, that is, that nearest the shoot.

Young seminal roots grown in nutrient solution may not be directly comparable with older nodal roots. The present experiments were conducted with plants of *Lolium perenne* a few weeks old which had been grown in soil and possessed several nodal roots. Just before the experimental treatments the roots were washed free from soil. All plants the roots of which showed signs of decay were rejected.

The absorption and translocation of phosphorus were studied using phosphorus-32. This was received carrier-free in dilute hydrochloric acid, which was added as required to the Hoagland solution. The plants were allowed to absorb the phosphorus-32 from this solution for 6 hr. The amount in the shoot tissue after this period was estimated by drying the material, digesting it with concentrated sulphuric acid and then measuring the activity of the resulting liquid, after making it up to a known volume.

In the first series of experiments, the ability of one portion of a root to absorb and translocate phosphorus-32 was studied. A portion of 12 mm. of one root of each plant was isolated by passing the root through a cellulose test-tube which had two holes opposite each other in its side. The junctions between the root and the test-tube were made watertight with simple ointment. Radioactive Hoagland solution (2 ml. with an activity of 5 μ c.) was put in the test-tube while the rest of the root system was bathed in normal Hoagland solution.

The results of one experiment with white unbranched nodal roots 10–12 cm. long are presented in Table 1. The basal region absorbed most phos-

Table 2. EFFECT OF CUTTING OFF THE ROOTS AT 2 CM. FROM THE BASE OF THE SHOOT ON THE UPTAKE OF PHOSPHORUS-32 AND ITS TRANSLOCATION TO THE SHOOT

	Uncut	Cut	S.E.
Shoot weight (gm.)	0.0705	0.0728	0.0041

Counts per unit weight	2.03	1.46	0.19
Total root weight (gm.)	0.0362	0.0337	0.0037
Weight of root cut off (gm.)	—	0.0259	—
No. of plants measured	12	12	—

phorus-32 which was translocated to the shoot. Similar results were obtained in other experiments.

The value of the basal portion of the root was confirmed by an experiment in which plants with intact root systems were compared with plants the roots of which had been cut off 2 cm. from the base of the shoot. The roots of both series of plants were immersed in Hoagland solution to which phosphorus-32 had been added to give it an activity of 100 μ c. per litre. Although the 'cut' plants had 77 per cent of their roots removed, the amount of phosphorus-32 reaching the shoots was only reduced by 28 per cent.

These experiments strongly suggest that it is from the basal portions of the roots that the shoot receives most of its phosphorus. The top few inches of the soil would therefore appear to be most important for the mineral nutrition of the plant. Boggie *et al.*³ found that grasses absorbed more phosphorus-32 from the upper 10 cm. of the soil than from greater depths.

According to Stout and Hoagland⁴ the phosphorus-32 would have to reach the xylem before it could be distributed throughout the plant. It would seem, therefore, that the thickened endodermis found in this region of the root⁵ was not an effective barrier to the inward movement of ions, as suggested by Weibe and Kramer¹. Alternatively, there may have been considerable downward movement of phosphorus-32 in the cortex either to the younger regions of the root where the endodermis was not thickened, as suggested by Soper⁶, or upwards to the junction of the root and shoot. If the thickened endodermis was an effective barrier, the plants with 'cut' roots in the second experiment must have absorbed the phosphorus-32 through the exposed xylem on the cut surface.

This work was carried out during the tenure of a New Zealand National Research Fellowship at the Department of Scientific and Industrial Research, Plant Physiology Unit, Grasslands Division, Palmerston North, New Zealand. Acknowledgment is due to Dr. K. J. Mitchell for help and advice.

BIOPHYSICS

Physico-chemical Properties of Purified Cytochrome a

THE enzymatic and spectral properties of purified cytochrome a isolated from animal tissues in soluble form have been studied by many investigators. However, a number of questions remain unanswered as to its physico-chemical properties. In previous

Fig. 1. Sedimentation pattern of cytochrome *a* in 0.1 *M* phosphate buffer containing 0.25 per cent 'Emasol 1130', pH 7.4. The direction of sedimentation is from left to right. The numbers under the photographs indicate the time in minutes after the rotor attained full speed (51,000 r.p.m.). The average rotor temperature was 16.4° and the protein concentration 0.54 per cent. (The small peak shown on the left may be due to detergent)

communications^{1,2} we have reported that a synthetic non-ionic detergent effectively reactivated purified cytochrome *a* while an ionic detergent was inhibitory. To study cytochrome *a* in an enzymatically active state in the presence of a non-ionic detergent, we have carried out various sedimentation experiments by ultracentrifuge. The highly purified cytochrome *a* preparation used in these experiments was prepared from ox heart muscle as described in the previous communication³. Cytochrome *a* was dialysed against 0.1 *M* phosphate buffer containing 0.25 per cent 'Emasol 1130' at pH 7.4 for 12 hr. The sedimentation pattern of cytochrome *a* in the presence of the non-ionic detergent, 'Emasol 1130', showed a single homogeneous and symmetric monodisperse component, as seen in Fig. 1, whereas in the presence of the ionic detergent, sodium cholate, the protein behaved as a polydisperse, aggregated system.

The sedimentation constant was determined at different protein concentrations and found to vary slightly with the protein concentration. A corrected value of $S_{20,w} = 21.9$ Svedberg units was obtained. Diffusion was measured on a preparation which had been dialysed overnight against the solvent system used for the sedimentation experiments. From results at different protein concentrations, the mean value was calculated as $D_{20,w} = 3.58 \times 10^{-7}$ cm.² sec.⁻¹. The partial specific volume was found to be 0.72 ml. gm.⁻¹. Combining these values in the familiar Svedberg equation, a molecular weight of 530,000 was obtained. The minimum molecular weight calculated from the haem, iron and copper contents was 100,000. Based on these results it is concluded that cytochrome *a* has about five molecules of haem and five atoms of copper per molecule of protein. However, Criddle and Bock⁴ recently succeeded in obtaining monomeric cytochrome *a* by treating a preparation with sodium dodecyl sulphate and estimated the molecular weight to be 72,000. Therefore, assuming that cytochrome *a* contains only one haem and one copper atom per molecule, it would be expected that some kind of polymerization takes place and a monodisperse pentamer of cytochrome *a* exists in the non-ionic detergent solution. To test this possibility ultracentrifuge experiments are now in progress in our laboratory. The frictional ratio f/f_0 was calculated to be 1.12. If the molecule is an unhydrated rotational ellipsoid, the axial ratio would thus be about 3:1. Further detailed results on the physico-chemical properties of cytochrome *a* will be reported elsewhere.

We wish to express many thanks to Messrs. K. Kakiuchi and T. Takagi of Isemura Laboratory of

this University for helpful advice on the physico-chemical measurements.

This investigation was supported in part by research grant RG-5871 from the Public Health Service of the U.S. National Institutes of Health, and by a research grant from the Institute for Protein Research, University of Osaka.

A Potentiometric Method for Observation of Osmotic Behaviour of Prawns

In the course of work on osmotic regulation of estuarine invertebrates, it was found that cryoscopic and vapour-pressure methods do not yield reproducible results in a tropical place such as Madras. The potentiometric method outlined here, which is based on the predominance of chloride ions in the blood of animals and in sea water, facilitates a continuous picture of changes in the concentration of the blood of an animal in a given medium and helps us to measure the amount of energy involved.

A simple concentration cell containing 2 per cent sodium chloride solution immersed in 0.5-4 per cent sodium chloride solutions registers potential differences varying from 0.5 to 30 mV., the e.m.f. developed being proportionate to the ratio of the difference in concentrations. When such a cell was used with sea-water of 16.2 per mille sodium chloride within the cell and sea-water varying from 4.05 to 32.4 per mille outside, it was found that in spite of the occurrence of other ions besides sodium and chloride, the silver-silver chloride electrodes used indicated potential differences varying in the same way as before. At the laboratory temperature (30° C.) the e.m.f. will be $60 \times \frac{87}{109} \times \log_{10} \frac{c_i}{c_o}$, allowing for the conductances of sodium and chloride ions and also the fact that the concentration and junction potentials are involved.

Table 1

Concentrations of outside media (per mille)		4.05	8.10	16.20	20.25	24.30	32.40
e.m.f. in mV.	Internal medium : sea water 16.2 per mille (observed)	27.24	13.68	0.30	4.86	8.12	13.56
	Internal medium : sea water 16.2 per mille (calculated)	28.40	14.38	0.00	4.65	8.34	14.38
	Internal medium : blood of prawn	23.60	11.70	3.01	0.31	2.10	7.60

Values calculated thus for the concentration differences are given in Table 1 along with values recorded by experiment. The e.m.f. increases by 14.5 mV. when the external concentration was doubled, as expected from the calculations.

In estimating the concentrations of the blood of the prawn in sea water of different salinities, a silver-silver chloride electrode is left in the container while the second electrode, shaped like a needle, is inserted in the heart of a live prawn, tied to a glass slide and left in the container. The results are given in Table 1. It will be seen that in spite of the blood having a protein concentration of 80 gm./litre¹, and is surrounded by different tissues as well as cuticular membrane, the e.m.f. values indicate the differences in concentration fairly closely. Since the e.m.f. recorded is lowest (0.31 mV.) when the prawn is left in sea-water of 20.25 per mille, the chloride concentration of the blood may be inferred to be the same as that of outside medium. It may be noted here that Panikkar and Viswanathan² found the chloride concentration of the blood of this prawn (*Metapenaeus monoceros*, Fab.) to be roughly 20 per mille, determined by the Volhard titration method as described by Wigglesworth. This method is now being used by one of us (O. R. R.) for work on osmotic behaviour of this prawn. Since the electrode is sharp and slender, the prawns can easily survive the injury in about eight out of ten cases even though they are used every day over a period of ten days.

We thank Dr. P. C. Caldwell, of the Marine Biological Laboratory, Plymouth, for his helpful criticism and Prof. O. Suryanarayanan, Department of Chemistry, Presidency College, Madras, for discussions on the subject.

BIOLOGY

Different Types of Body Movement in the Hagfish, *Myxine glutinosa* L.

FROM the systematic and anatomical points of view, Myxinoidea are well known¹⁻⁴; but there are as yet only short notes about their living habits^{2,4,5}. During the summer of 1959, I had the opportunity of examining living hagfishes at the Universitetets Biologiske

Stasjon Drøbak in the Oslofjord, Norway. I observed about 200 hagfishes living in aquaria and also freshly captured specimens.

Observations on the habits of hagfishes will help in describing the life-history of these animals. I propose to report here particularly the movements of the animals when disturbed in their self-produced slime masses. There are to be distinguished complicated moving patterns of the body of the hagfishes, the result of which is the cleaning and liberation of the surface of the body from adherent slime. This cleaning seems to be of essential importance for a normally functioning respiratory stream from the nasopharyngeal duct to the gills.

The animals were captured by means of eel-pots furnished with fish as bait⁵. Most of the observations were made with hagfishes captured from a depth of about 50 metres in the Oslofjord near Drøbak, also some at the Biologiske Stasjon Espeland near Bergen in western Norway. Freshly captured animals were put as quickly as possible into aquaria furnished with sea water of a medium temperature of about + 8° C. In the aquaria there was a continuous flow of new sea water taken from a depth of 30-50 metres.

Normally the hagfishes lie nearly the whole time at the bottom of the containers, most of them stretched out, some rolled up. Animals disturbed by touching with a stick move in lively fashion for some minutes but return shortly after the end of the stimulus to their usual motionless position. Hagfishes which have not been fed for some days become very active as soon as food is offered, for example, small herring, annelids, etc.

The hagfishes show normal locomotion movements comparable to those of eels, snakes or worms. The body of the animal makes sinuous swaying movements caused by alternate contractions and relaxations of opposite muscle segments of the body (compare Fig. 1). Usually the animals move forward with the head as the front pole. But often, especially if touching an obstacle, for example, the wall of the container or another animal, the movement may be reversed so that the tail end becomes the front pole of movement. Also under such conditions of backward swimming, snake-like swaying occurs. The plane of the swaying movement is often, but not always, horizontal. Locomotion is possible in all directions of space with the same accuracy. Sometimes a sort of rotation along the main body axis is observed, giving an impression comparable with driving a screw.

Fig. 1. Normal snake-like swimming movement in the hagfish

Excited animals—for example, after repeated stimulation by a stick, but also spontaneously in the case of animals disturbing one another by slime production (for example, in crowded containers)—show other types of movement besides the normal snake-like swaying. These special movements are in most cases connected with the liberation of the animals from slime masses covering their body surface.

Roughly two types of special movements can be distinguished: (1) The simpler one consists in a repeated rather narrow figure-of-eight movement of the body along the main body-axis. The general impression is similar to the usual snake-like type of locomotion, but the animal does not move forward or very little (Fig. 2). (2) The second type is more conspicuous and, I believe, is connected with a more intense excitement of the animals. At first the hagfish forms a loop by means of the end of its tail (Fig. 3). The loop remains close to the surface of the body and in the following stage of the movement the whole body is pulled through the loop, thus wiping away the slime from the surface of the body. The direction of this type of movement is from the tail towards the head. After passing the mouth and the nostril the loop opens again. The general impression of this type of movement is that of 'knotting' the body. The time necessary for one knotting movement is about 2-3 sec. Such knotting-movements are normally performed twenty times or more. After having finished with knotting, the animal swims off, moving then in the normal snake-like manner, and after some seconds or even minutes of swimming it comes to rest again in the usual manner at the bottom of the container.

Both types of special movements (figure-of-eight motion and knotting) are, according to my observations, always connected with intense excitement of the animals and are therefore to be regarded as 'excitement movements'. Intense excitement in most cases leads to the production of large amounts of slime. The types of movement described therefore serve to liberate the animals from self-produced slime, and also from slime produced by other members of the species or disturbing agents. Slime seems to be dangerous to the animals not only mechanically but also by the interruption of the water-stream from the nostril through the craniopharyngeal duct into the gills and thus causing cessation of 'breathing'. Before performing the special movements, the animals are often as it were exhausted; but after repeated 'knotting' and 'figure-of-eight motion' their bodies assume their normal motion.

The two types of special movements are performed in different positions of the body in relation to the bottom of the container, mostly of course in a general horizontal position.

It is obvious that these patterns of movement with their exact step-by-step decrease have a functional

Transplantation of Mammary Glands

I WISH to describe two methods I have used of transplanting whole mammary glands in goats. The work was undertaken so that mammary function could be studied in conscious undisturbed animals, by experimenting on one gland and comparing it with the control gland on the same animal. Anaesthesia reduces the rate of milk secretion, and it is not easy, for example, to make repeated flow measurements or arterial infusions in conscious goats because the main artery is difficult to exteriorize effectively. By transplanting one gland on to another site on the animal, the main artery and vein are made readily accessible. It is well known that mammary growth and milk secretion can take place after the nerves to the tissue have been removed, and it is generally

Fig. 1

believed that these processes are almost entirely controlled by hormones. Although Ribbert showed in 1898¹ that small pieces of mammary tissue survive autotransplantation and show histological signs of normal growth and function, there have been no reports of the transplantation of whole glands nor of the quantitative measurements of growth and lactation of denervated tissue that are possible with the present methods.

The first results were unexpected since apparently successful transplants made in young kids failed to grow normally during pregnancy and yielded much less milk than the control glands in the normal situation. This was reminiscent of the long-term deficiencies following section of the spinal or sympathetic nerves to mammary tissue reported in some laboratories². With modifications in technique, other transplanted glands have grown almost normally and the maximum yields have reached 70–90 per cent of the controls during lactation.

(1) *Transplantation in 2 or 3 stages.* By this method the gland was moved in stages to its new site (on the side or back) in such a way that it always retained a vascular link with the animal. It has been done in four virgin animals just before the first pregnancy, and in one animal at the end of the first lactation (Fig. 1). At the first operation one gland (half the udder) was separated from the body except for the skin at its front and the caudal superficial epigastric vessels ('milk' vein and artery) lying beneath this skin. These vessels were thus the only source of blood, and since they anastomose with the cranial superficial epigastric vessels emerging through the abdominal wall by the xiphoid, once they had enlarged, the result was a gland supplied by a readily accessible artery and vein each 25–30 cm. long. During this phase the gland was replaced in the normal position for 3 weeks and then again dissected out on this long pedicle right back to the xiphoid region. A piece of skin the size and shape of the gland was removed over the last rib and the gland was pulled into this space by tunnelling under the skin, and then stitched into place. Although it is almost certain that the entire nerve supply is cut by these two operations, in one goat the caudal superficial epigastric vessels were resected at a third operation three weeks later. In another the artery was exteriorized as a skin-covered loop which has remained patent for two years.

(2) *One stage transplant.* This has been done only in two goats, both in full lactation. In both cases

one gland was removed entirely from its normal site and stitched on to the ventral surface of the neck (Fig. 2), the main artery and vein being joined to the carotid artery and the external jugular vein respectively. The control gland was pulled over to close the gap left in the inguinal region and now lies in the midline. In the first animal the caudal superficial epigastric vessels were joined to the omocervical vessels with polythene cannulae within 16 min. and the main vessels were anastomosed within 100 min. to the carotid and jugular end-to-side by Phelan's trapdoor technique³. The carotid was tied above the join one month later. In the second animal the vessels were joined end-to-end in 36 min. using 1 cm. long stainless steel Payr cannulae outside the mammary vessels and then stitched. This animal was then given one dose of heparin (1,000 u./kgm.). At both operations the main efferent lymph duct was cannulated and brought to the exterior. However, after the operation the lymph-flow slowed down markedly, probably associated with general anaesthesia⁴, and to prevent clotting the cannulae were removed. A defective lymph drainage may be why both transplants became more swollen than the controls. Whereas the milk yields of the controls recovered within 4 days, the transplants took 10 and 16 days and are still slightly oedematous 6 weeks after the operation. It should be possible to exteriorize the mammary vessels later.

Some observations made on all these goats may be mentioned. The 2-stage technique is easier to apply to virgin animals but, at best, glands transplanted in this way have given only 70 per cent of the expected milk yield. Furthermore, in one animal a decrease in yield was seen in the second lactation after the

Fig. 2

transplantation and there is some evidence to suggest that the transplanted gland is affected by the presence or absence of the control. The newly acquired blood supply may well be inadequate. For this reason the one-stage technique would seem to be better and the milk yields of the two animals investigated are 75 and 90 per cent of that expected six weeks after the operation although the long-term results are not yet known. The operative technique could be improved by joining the blood vessels much more quickly and anastomosing the lymph duct to the lymphatics of the neck. In contrast to denervated glands or to those transplanted back into the normal site, when regeneration of sensory nerves has been fairly extensive during the course of pregnancy, the glands transplanted in two stages have remained completely anaesthetic for up to 2 years. In one animal tests made 2 years after transplantation showed that a small number of vasomotor nerves had entered the gland with a new artery that had grown in from the surrounding skin. In none of the animals has it been possible to initiate milk ejection or rumination by milking the transplanted teat. In cases where both glands were transplanted (1 animal) or the control gland was removed (2), lactation proceeded in the apparent absence of milk ejection. By injecting oxytocin intravenously (200 mu.) during each milking for a week at various stages of lactation it was possible to assess the importance of milk ejection; in this way it was found that 80-98 per cent of the milk may be obtained in the goat without it. Tverskoy⁵ also noted that after complete denervation of both glands in one out of four goats the complete yield could be obtained without oxytocin.

Further work is in progress to try to decide to what extent the residual deficiencies noted may be due to impairment of the blood supply and lymph drainage.

Inflation of the Neck Pouch of the Marabou Stork

THE pouch of the marabou stork (*Leptoptilos crumeniferus* (Lesson)), was described by Peters¹ and its nature investigated by Chapin². Chapin concluded that the pouch was inflated by means of air from the left nostril being driven into a pair of thin-walled sacs in the neck.

Detailed dissection of specimens collected in the Nairobi area have revealed a complicated valvular mechanism in the left nasal organ, which directs air from the lungs into the neck sacs during exhalation. The left and right air sacs are inflated through the left nostril, air being directed by a series of valves behind and below the eye-ball and through a narrow passage over the pterygoid. This passage leads into the left air sac, which in turn communicates with a smaller

sac on the right side of the neck. The left nasal organ is divided into two chambers, one leading directly from the external to the internal nares, and a second inflation chamber which leads from the external to the internal nares and also to the orbital passage by means of a valvular opening. The right nasal organ is similar but bears no opening to the orbital passage. Although this opening is closed, the passage and the pterygoid duct are both present.

Inflation of the neck pouch is accomplished in the following manner:

(1) *Inhalation*. Air is drawn into the lungs through the external nares, passing through either the nasal or the inflation chamber.

(2) *Exhalation*. When the air sac is to be inflated, the nasal chamber and the entrance to the inflation chamber are closed by means of a sphincter and a small constrictor muscle. When air is exhaled from the lungs it enters the ventral opening of the inflation chamber; whence it is directed by a concave valve through the posterior opening to the orbital passage and the air sac.

Isolation of Transplantation Antigens from a Cultured Lymphoblast L-5178Y

EXPERIMENTS designed to characterize the nature of the transplantation antigens have been greatly hampered by the difficulty of obtaining large amounts of a homogeneous starting material. We would like to report the successful isolation of transplantation antigens from a mammalian cell cultured *in vitro*.

Fischer¹ has shown that a lymphoblast, L-5178Y, that originated as a spontaneous leukaemia of thymic origin in a DBA/2 mouse can be grown in tissue culture. The cells do not stick to glass and can, therefore, be grown easily in suspension. In the medium reported by Fischer, yields of 2-3 gm. wet weight per litre are routinely achieved. The cells grow logarithmically *in vitro* and in the ascitic fluid of a DBA/2 mouse with an 11.4-hr. generation time, and can be transferred from one condition to the other with an adaptive lag in growth of less than 24 hr.

Adult C₃H mice immunized with 10,000 L-5178Y cells reject an intraperitoneal challenge of 2×10^6 L-5178Y cells, a dose that results in abundant growth of an ascitic tumour which is fatal to 23 per cent of the non-immunized controls. Such immunized C₃H mice also show an accelerated rejection of a graft of DBA/2 skin on the tail². Test grafts of C57 BL skin on the tails of both immunized and non-immunized C₃H mice are rejected at the same time, 10-15 days, indicating that L-5178Y contains antigens specific for the DBA/2 strain.

The antigenic substances were isolated in a soluble form and attached to particulates from freshly harvested L-5178Y cells grown *in vitro*. The fractionation procedure is based on the methods used by Billingham, Brent and Medawar³ with spleen and thymus cells. Cells were suspended in distilled water, and treated in a Raytheon 10 kc./sec. sonic oscillator

Table 1. RESPONSE OF *C₃H* MICE TO IMMUNIZATION WITH WHOLE CELLS AND CELL-FREE EXTRACTS OF *L-5178Y* CULTURED *in vitro*

Antigenic material	Tumour challenge			Skin graft test		
	No. of mice tested	No. of survivors	No. of survivors	No. of mice tested	Median survival time of grafts (days)	
		Showing ascitic growth	No detectable ascitic growth		DBA/2	C57BL
Control	30	22	1	5	13	12
Whole cells	10	0	10	6	6	—
Crude suspension	12	1*	11	4	7	—
Deoxyribonucleoprotein fraction	10	4*	6	6	7	12
Microsome fraction	10	2*	8	6	6	12
Soluble fraction	17	4*	13	7	6	13
pH 5 precipitate	10	2*	8	6	7	12

* The amount of ascitic growth found in these cases was always much less than that seen with controls tested at the same time.

in the cold for 1 min. at full power. After centrifuging for 10 min. at 3,000*g* to remove debris, the crude suspension was made 0.15 *M* in sodium chloride, and allowed to stand for 1 hr. in the cold. The pellet obtained after centrifuging for 10 min. at 5,000*g* consisted mainly of deoxyribonucleoprotein of the cells. The supernatant suspension was centrifuged for 1 hr. in the Spinco ultracentrifuge, model *L*, at 105,000*g*. This precipitate (microsomal fraction) and the soluble fraction were tested separately for antigenic activity. Each fraction was injected intraperitoneally into adult *C₃H* mice, so that each mouse received the extract from 1.5×10^8 cells. Five days later, the animals were challenged by each of the test procedures outlined above. Antigenic activity, that is, protection of *C₃H* mice from a challenge dose of *L-5178Y* and an accelerated rejection of *DBA/2* skin (Table 1), was found in each of the three cell fractions to about an equal extent. Whether the antigenic material in each fraction is chemically different or whether equal amounts of the same antigen are distributed among the three fractions has not yet been elucidated. What is interesting to note is that we obtained an antigenic response to 1.5 mgm. of a soluble proteinaceous material in both tests. In several experiments the antigenic material was found to precipitate after 24 hr. in the cold when the soluble fraction was adjusted to pH 5. Castermans and Oth³ have also reported the isolation of soluble antigenic material from the nuclei of mouse spleen and thymus cells.

A detailed report on the chemical properties of active fractions and the animal test procedures used will be presented at a later date.

This work was supported in part by grants E-88 and E-89 from the American Cancer Society and United States Public Health Service research grant 2G-142 (National Cancer Institute).

Gibberellin and Sex Differentiation of Flowering Plants

THOUGH work on the influence of gibberellin on flowering of plants has been given much attention, up to now very little is known about the relation of gibberellin to sex differentiation of plants.

My experimental work was carried through with hemp (*Cannabis sativa* L., var. Rastislavická). Gibberellin was applied in aqueous solutions containing 5, 10, 25 and 100 p.p.m. The seeds were allowed to soak in the solutions 24 hr.; controls were in distilled water for the same time. The number of individuals in the different variations of the experiment ranged between 400 and 500, all variations of experiments being repeated twice. When examining the results I noted first of all the relation of gibberellin (a) to sex differentiation, (b) to growth of female and male individuals.

As to the relation of gibberellin to sex differentiation, an increasing percentage of female individuals following treatment with gibberellin was observed. The highest increase by 113.9 per cent (with regard to control plants) was registered with concentration 10 p.p.m.

Proportions of male and females plants ($x = \frac{a\delta}{a\delta + \beta\delta}$) after application of gibberellin were as follows:

control plants	$x = 1.07$
application of gibberellin at 5 p.p.m.	$x = 0.99$
10 p.p.m.	$x = 0.82$
25 p.p.m.	$x = 1.05$
100 p.p.m.	$x = 1.04$

When comparing the average length of stems of female and male plants at the end of vegetative growth, different reaction of female and male plants to various concentrations could be traced, both with respect to stimulating (lower concentrations) and inhibitory (higher concentrations) effect. To a greater extent the stimulating effect was shown on female plants where the maximum of stem elongation was 107.8 per cent with a concentration of 5 p.p.m., the maximum elongation on male plants being 106.5 per cent at 10 p.p.m. (percentage given with regard to control plants). The inhibitory influence of higher concentrations (25 and 100 p.p.m.) was manifested in a greater measure with female plants. Induction of male sterility, however, was not observed; male plants showed normal development after application of gibberellin.

Because of the close relation of gibberellin to the synthesis of growth substances, as well as on grounds of observations made by Laibach and Kribben^{1,2} and by others, according to which sex expression of female and male flowers depends on the concentration of growth substances in the organism, it may be presumed that the observed reduction of percentage and the higher growth inhibition in male plants and, on the contrary, the increase of percentage, the higher stimulatory and lower inhibitory effect in female plants, after application of various gibberellin concentrations is related in some way to the synthesis (to various concentrations) of growth substances in female and male plants. Their increased production (dissolution) from some precursor or their destruction after gibberellin treatment (especially at higher concentrations) is probably capable of influencing the biochemical processes of female and male plants considerably, which may find expression—as the observations mentioned show—not only in processes

of growth but also in the process of sex differentiation itself.

The gibberellin used in these experiments was obtained through the courtesy of the Kyowa Fermentation Industries, Tokyo, and Plant Protection, Ltd., Fernhurst Research Station, nr. Haslemere, Surrey, England.

Effect of Growth Substances on the Osmotic Value of Pea Stem Sections

It has been shown that gibberellin does not increase the extensibility of the pea stem, while auxin does^{1,2}. It thus remains to show whether gibberellin increases the osmotic concentration in cells, so as to increase water absorption. As to the effect of auxin on the osmotic concentration, conflicting results have been reported³⁻⁵. The present communication reports some experiments which reveal that gibberellin causes catatonosis while auxin causes anatonosis.

Pieces of stem, 10 mm. long, excised from an apical part of the third internode of etiolated Alaska pea seedlings were weighed and soaked in 20 mgm./l. solution of gibberellin (composed of A₁ 4.5 per cent and A₂ 90.0 per cent), 10 mgm./l. solution of indole-3-acetic acid or distilled water. After being floated on the solutions or water for 3 and 6 hr. at 25.5°C., the stem pieces were lightly blotted and packed in weighing tubes to prevent loss and condensation of moisture during weighing and freezing (at about -21°C.) to follow. After melting, tissue juice was obtained using a hand press. Freezing point of the juice was measured using a copper-constantan thermo-junction and potentiometer to the nearest 0.01°C.

Freezing-point depressions measured are presented in Table 1. The molar concentrations (w/v) of mannitol solution corresponding to them were determined by using a standard freezing-point curve prepared experimentally, and given in Table 1.

Let the water content of stem pieces be H and βH respectively before and after the treatment; and

Table 1. Effects of gibberellin and indole-3-acetic acid solutions on freezing point depression of press juice, factor of water absorption, and factor of change in the amount of the osmotically effective solutes, when etiolated pea stem sections were floated on the solutions

	Freezing point depression (°C.)	Mannitol equivalent (M (w/v))	Water absorption factor (β)	Solute factor (α)
Before treatment	0.60	0.30	—	—
After treatment for 3 hr. with				
Water	0.48	0.24	1.14	0.91
Indole-3-acetic acid (10 mgm./l.)	0.38	0.19	1.36	0.86
Gibberellin (20 mgm./l.)	0.44	0.22	1.15	0.84
After treatment for 6 hr. with				
Water	0.44	0.22	1.18	0.87
Indole-3-acetic acid (10 mgm./l.)	0.29	0.15	1.57	0.78
Gibberellin (20 mgm./l.)	0.40	0.20	1.21	0.81

let the virtual amount of the 'solute' contributing to the osmotic concentration of tissue juice be S and αS respectively before and after the treatment. Then, the osmotic concentration of press juice is $C_0 = S/H$ before the treatment, and $C_1 = \alpha S/\beta H$ after that. The solute change factor, α , is given by:

$$\alpha = \frac{C_1}{C_0} \beta \quad (1)$$

C_0 and C_1 are represented by mannitol values. The water-absorption factor, β , is the ratio of the amounts of water (βH and H) which are determined by subtracting from the fresh weights the dry weight of the tissue. The last-named was estimated with the same stem pieces as used in the experiment.

The values of β in Table 1 show that pieces treated with indole-3-acetic acid absorbed more water than control, while those treated with gibberellin did not. On the other hand, the 'solute' contributing to the osmotic concentration of tissue decreased more conspicuously with indole-3-acetic acid and gibberellin treatments than water control. In these experiments, however, solutes may have diffused out of the tissue into treatment solutions. Hence, in order to determine if catatonosis is really caused by indole-3-acetic acid and gibberellin, stem pieces were kept in air of constant humidity, instead of being put in the solutions.

Air equilibrated with the saturated solutions of magnesium sulphate and potassium phosphate and with distilled water is considered to be of about 90 per cent (ref. 6), 96.8 per cent (ref. 7) and 100 per cent humidity, respectively, at 25°C. Pieces of stem were smeared at both ends with lanolin pastes of 1 per cent gibberellin and of 0.5 per cent indole-3-acetic acid, as well as with pure lanolin. They were incubated under slow circulation of the above-mentioned air for 3½ hr. at 25.5 ± 0.01°C. The fresh weight of these pieces (carrying the lanolin) were determined before and after the incubation, and press juice was obtained from the pieces after the

Table 2. * Water absorption factor less than unity represents loss of water.

† Elongation effect of indole-3-acetic acid was rather small in this experiment made in winter, as is usually the case.

parts smeared with lanolin were cut off. The results are shown in Table 2.

The moisture contained in the pieces decreased slightly even in air of 100 per cent humidity. This may perhaps be due to evaporation during the transfer to and from the container for incubation. The pieces treated with indole-3-acetic acid had high osmotic concentration, the solute increase being large. The gibberellin treatment, on the contrary, caused a decrease in the 'solute'. It is therefore suggested that anatonosis is caused by indole-3-acetic acid, and catatonosis by gibberellin.

It has often been shown that indole-3-acetic acid increases extensibility of the cell wall. Together with this, the fact that anatonosis is caused by indole-3-acetic acid presents a simple hypothesis which can explain the way this acid causes elongation. On the other hand, gibberellin rather causes catatonosis, and, as has been reported^{1,2}, makes pieces of stem elongate less under a stretching force. Hence the mechanism of action of gibberellin should be sought from some other point of view.

Protein from Sugar Cane

SUGAR cane is a major crop in many areas of the world where there is also malnutrition, particularly a shortage of dietary protein, and a high birth-rate. It is important that these areas should exploit to the full any potential source of protein for human diets, either to be consumed directly or indirectly through animal feeding.

Pirie has canvassed widely for more attention to the potentialities of leaf protein extraction, but sugar cane leaves, in common with the leaves of all high-yielding crops, are very low in protein, containing only about 6 per cent on a dry-matter basis.

The basis of extracting leaf proteins is maceration, filtration and coagulation. This scheme is almost followed by sugar factories for preparing the cane juice prior to its concentration, the heat-coagulated protein being filtered off along with other solids to give filter cake which may be returned to the fields as a soil amendment or even dumped as waste.

The heat-coagulable nitrogen content of cane juice is very small, but nevertheless the quantities involved during a crushing season are high.

Mauritius, with an annual crop of around 550,000 tons of sugar, produces about 100,000 tons of filter cake with a nitrogen content of 1 per cent. In other words, about 6,000 tons of cane juice 'protein' are returned to the soil each year as a fertilizer in a country where protein-deficiency symptoms are common among the population.

In the laboratory it is simple to produce a precipitate containing up to 8 per cent nitrogen from cane juice; on a factory scale, however, the problem is more difficult.

Much work has been done in cane-producing countries on the separation of cane-wax, but no process has yet proved to be economical. As the coagulate formed in cane juice on heating carries much of the wax with it, a combination of protein and wax recovery may prove to be financially interesting.

Research work is in progress in Mauritius to study the amino-acid composition and nutritional values of the heat-coagulated precipitates and the technological aspects of their separation. The full results of this work will be published later.

Microspectrophotometry of *Euglena* Chloroplast and Eyespot

A SIMPLIFIED microspectrophotometer developed in our laboratory was applied to obtain the *in vivo* absorption spectra for the chloroplast and eyespot of the algal flagellate *Euglena*. The optical and electrical characteristics of this instrument, which utilizes a Bausch and Lomb grating monochromator and a cadmium selenide photoconductive cell, have previously been reported¹.

Euglena gracilis Z strain (obtained originally from Dr. S. H. Hutner, Haskins Laboratory, New York) cultured in a chemically defined medium under continuous fluorescent light (300 ft.-candles) in a temperature-controlled room of 25° C. was used for this work. Samples of *Euglena* were taken, during their log-phase of growth, from the culture bottles, placed on a microscope slide with the edges of the cover-glass sealed with 'Vaseline' to prevent drying-out of the organism and pressure applied in order to immobilize them. No further preparation or staining was employed. The prepared *Euglena* slide was immediately placed on the microscope, a chloroplast or eyespot was selected and focused for scanning with the microspectrophotometer. The reference area was the suspending medium adjacent to the organism; the half-band width of the incident radiation was 4.6 mμ. The green chloroplasts measure about 1μ in diameter by about 10μ in length². The orange-red eyespot is 1-2μ in diameter by 3μ in length; it consists of packed granules and is close to its effector, the flagellum^{3,4}.

In Fig. 1a, the absorption spectrum of an individual chloroplast over the wave-length range 250-340 mμ is illustrated. The results are presented as percentage absorption for intervals of 10 mμ. This spectrum is matched at 340 mμ with another chloroplast spectrum, Fig. 1b, extending to a wave-length of 700 mμ. Except for small changes in relative peak heights, the results were consistent from one chloroplast to another within the same organism as well as in different organisms under the same condition of time of growth and light intensity. These chloroplasts have two major absorption peaks, one in the region 430-435 mμ and the other in the region 675-680 mμ with minor peaks near 485, 585 and 620 mμ. The peaks were

previously noted from absorption spectra on cell suspensions of *Euglena*³, although fine-structure details and the spectra from individual organelles were not obtainable. Among the absorption peaks listed above, the 485 m μ peak is known to be due to carotenoids, while the others are due mainly to chlorophyll *a*, which has peaks at 432, 480 and 665 m μ in methanol. In following the absorption peaks with culture age, changes in the 415–435 m μ as well as new peaks appearing at 685–690 m μ could be observed. In the ultra-violet region, an absorption peak in the region 265–270 m μ with lesser peaks at 290, 340 and 390 m μ would indicate that the chloroplasts contain proteins and lipids.

The eyespots of *Euglena* were investigated in the visible range, 400–700 m μ . The reference area in this case was the cell cytoplasm or the vacuole adjacent to the eyespot. The spectrum for an average eyespot is illustrated in Fig. 2. In contrast to the chloroplast spectra, the eyespot results exhibited appreciable variation in peak height from one eyespot to another. They show that the eyespot has a broad absorption maximum in the region 480–490 m μ , two sharper maxima at 420 and 530 m μ respectively, and lesser peaks at 430 and 630 m μ . An absorption peak at 450–460 m μ was noted for several eyespots, and is shown as a shoulder on the curve in Fig. 2. This spectrum is in qualitative agreement with that obtained by Gössel using a microbeam larger than the eyespot cross-section⁴. The eyespot therefore absorbs light throughout the entire visible range. The action spectra for *Euglena* phototaxis has peaks at 420 and 490 m μ , and for photokinesis (rate of swimming irrespective of direction) has peaks at 465 and 630 m μ ⁵. The eyespot absorption spectrum therefore contains these same peaks as do the action spectra. The interpretation of Fig. 2 with respect to the identity of the pigments present in the eyespot is, however, difficult. Normal green strains of *Euglena gracilis* produce three main carotenoids: β -carotene, lutein and neoxanthin. In a non-polar solvent, carbon disulphide, the absorption range of these carotenoids is 450–510 m μ . These carotenoids could therefore account for a major proportion of the observed absorption. However, astaxanthin, which has a broad absorption band at around 500 m μ and has been found in red variants of *Euglena*, and not

Fig. 2. *E. gracilis* eyespot average absorption spectrum

identified here, could be masked by the above carotenoids.

This work was aided in part by grants from the United States Public Health Service Institute of Neurological Diseases and Blindness (B-397 C5, B-1874-A) and the Stoner-Mudge Foundation. This work will be published in greater detail (*J. Protozool.*, 1961).

MICROBIOLOGY

An Improved Method for photographing Superficial Microbial Colonies

THE lack of contrast in transparent superficial microbial colonies causes some difficulties during photography. The following method promises good results provided some precautions are taken. Suppose it is intended to photograph transparent, colourless colonies on nutrient agar plates. The surface of the medium is flooded with indian ink diluted in distilled water (1 : 100). The ink contains a pigment, carbon black, having a particle size of 200 Å. (Pelikan Tusche No. 541, Günther and Wagner, Hanover). When the upper layer becomes coloured (about 2–3 min.), the surplus solution is sucked off. As a result, in the weakly coloured medium the colonies remain colourless and in a photograph the distinction is clearly visible (Fig. 1). The principle of this procedure is founded on the slower penetration of coarse-grained colloid into the colonies and may be considered as the macro-adaptation of Burri's indian ink 'negative staining' method¹. One must be careful to work

Fig. 1. Colourless and transparent colonies of *Salmonella paratyphi B* after treatment with diluted indian ink

quickly before the colonies become coloured and the dish should not be stirred because the colonies easily emulsify. The use of crossed 'Polaroid' filters or 'Polaroid J' film (Fisher Scientific) under and over the dish gives more contrasted pictures. As light source, an X-ray illuminator is suitable.

The advantages of the method seem to be at first in its application for the photographic documentation of colony counts, and for the visualization of small transparent colonies.

CYTOLOGY

Determination of Sex in Granulopoietic Cells of Mice and Rats

WHILE examining Feulgen-stained sections of rat bone-marrow, it was observed that certain granulocyte precursors showed a body strongly resembling the sex chromatin described in other species¹ in that it occurred with much greater frequency in female than in male marrows.

In the initial work on the sex chromatin¹ it was not found possible to identify this body in rodents because of the coarse clumping of nuclear chromatin in the central nervous system, with which these studies were largely concerned. More recently, however, it has been shown that sex chromatin bodies may be demonstrated in those rodent tissues where the nuclear chromatin is sufficiently dispersed, for example, in liver cells^{2,3}, certain neurones⁴, ameloblasts⁵, amnion cells³, cells in tissue culture⁶ and a small proportion of peripheral blood leucocytes⁷ in rats, and in neurones and liver cells in hamsters^{3,8}.

Accordingly, in view of the value a sex chromatin body could have as a marker in studies involving marrow transfer, the observations mentioned above were extended.

Colony-bred mice of A2G, C57 and AK strains and rats of the WAG and PVG strains were used⁹.

Femoral marrow was fixed in glacial acetic acid/ethanol (1:3) for 1 hr., re-suspended in water for 5–10 min., hydrolysed in *M* hydrochloric acid at 60° C. for 10 min., treated with Schiff's solution for 45 min. and transferred to chilled 45 per cent acetic acid. Permanent 'squash' preparations were made by the quick-freeze method¹⁰.

A preliminary survey suggested that attention be concentrated on the cells classified by Harris and Burke¹¹ as 'typical metamyelocytes', large cells with ring- or doughnut-shaped nuclei, often with one or two nucleoli and showing, in Romanowsky-stained films, a few azurophil granules. In 'squash' preparations many of these cells show chromatin sufficiently dispersed to make observation of a sex chromatin body feasible. Only those cells were considered in which, apart from the bodies to be described, the chromatin was well dispersed, the nucleus showing a homogeneous lilac-stained background overlain by a finely condensed reticular or stippled pattern. Sometimes a few tiny splinter-like or nodular condensations were present, usually at the nuclear margins. Nuclei were excluded from consideration in which a sex chromatin body could not have been identified confidently had it been present, that is, the chromatin of which was coarsely reticular or nodular or that contained several small (less than 1 μ in diameter) but deeply stained chromatin bodies, or more than one large chromatin aggregate or that were vacuolated. Nuclei which were damaged or overlapped by others, or were tilted or folded so that the position of a chromatin body could not be determined accurately, were also excluded.

Fairly conspicuous chromatin bodies were seen in some of the nuclei satisfying the above criteria; they stained with varying intensity and measured about 1/6–2/3 of the width of the nuclear sector in which they lay. They were usually solitary but nuclei were, for the purposes of this work, accepted as having such a body if they contained not more than one other appreciably smaller chromatin aggregate.

These bodies were either applied to the outer or inner aspect of the nuclear ring or lay free within the nucleus. In all positions their shape could be irregular, but usually they were triangular, trapezoidal or oblong if applied to the nuclear membrane and round or oval if lying free (Fig. 1). Peripherally situated bodies were sometimes bifid¹². Bodies in other positions were often closely associated with a nucleolus.

Marrows were taken from three males and three females of each of the strains listed above, and all specimens were coded so that the sex of the animals was unknown until the results had been collected.

PVG	1	34	10	28	28
	2	34	12	38	16
	3	44	6	16	34

Fifty nuclei were counted in each marrow and the presence or absence of a chromatin body and its position were recorded. Simple inspection of the results showed that marrows could be grouped into two non-overlapping classes: those in which the peripherally situated chromatin body occurred in 30–52 per cent of nuclei and those in which its incidence did not exceed 2 per cent. It was found that all the marrows in the former class were from females and all the latter from males. The results are summarized in Table 1. There was no clear sex difference in the incidence of chromatin bodies in other positions.

It can be concluded that the sex of mouse and rat metamyelocytes may be determined by the incidence of peripherally situated chromatin bodies, a finding that may be of use in studying the fate of inter-

specific, inter-strain and intra-strain transfers of marrow.

The photographs were taken by Mr. D. F. Boxall.

Cytology of *Polygala*

COMPARATIVELY little is known of the cytology of the genus *Polygala*. Table 1 gives chromosome counts made on ten European and one South African species, together with previous counts for comparison.

The chromosomes of the *vulgaris-amara* group are very small but not uniform in size (about 0.5–1 μ in somatic plates). Those of *P. monspeliaca* are yet smaller but seem more uniform, while those of *P. myrtifolia* are a little larger and not uniform. The chromosomes of section *Chamaebuxus* range from about $\frac{2}{3}$ to 4 μ in length. The resting nuclei of the *vulgaris-amara* group are chromocentric, while those of *Chamaebuxus* have an abundant reticulum with some chromocentres⁷.

In the *vulgaris-amara* group, apart from one rather larger bivalent in *P. calcarea*, individual chromosomes within the complement cannot usually

<i>P. chamaebuxus</i> L.	6	—	$2n = c. 46$	—	$\begin{cases} n = 23 \text{ (ref. 7)} \\ 2n = 38 \text{ (ref. 4)} \end{cases}$
<i>P. vayredae</i> Costa	1	—	—	$2n = 28$	—

'*P. oxyptera*' is included under *P. vulgaris*, and does not differ from it cytologically. The British '*P. austriaca*' (Kent) and '*P. amara*' (Yorkshire) are included under *P. amara* spp. *amarella*.

'Other' localities are as follows: *P. calcarea*, St. Andrews Botanic Garden (thought not British material); *P. serpyllifolia* (tetraploid), Corsica; *P. vulgaris* and *P. monspeliaca*, Portugal; *P. myrtifolia*, Antibes Botanic Garden; *P. vayredae*, horticultural, ex. Lausanne.

be picked out. Some of the larger chromosomes in *Chamaebuxus* can be recognized, however⁷. The largest two in the haploid set of *P. vayredae* have subterminal centromeres and resemble two in *P. chamaebuxus*, and a third nearly as large in *P. vayredae* has a median centromere and again could correspond to a chromosome in *P. chamaebuxus*, but two long chromosomes with terminal centromeres in *P. chamaebuxus* are not present in *P. vayredae* so that while *P. vayredae* may be a parent of *P. chamaebuxus*, a second parent must have contributed these latter chromosomes.

While previous work has suggested a less-orderly situation, the present work indicates that most species of the *vulgaris-amara* group are diploid with $n = 17$, *P. serpyllifolia* has both a diploid and a tetraploid race, and *P. vulgaris* is tetraploid with $n = 34$. Two less-closely related species of section X, *P. monspeliaca* and *P. myrtifolia* (a South African shrub), appear to have $n = 19$, which corresponds with Hagerup's⁸ count on *P. erioptera*. In section IX (*Chamaebuxus*) two seemingly unrelated numbers have been found ($n = 14$ and 23).

Previous counts, except that by the Löves⁶ ($2n = c. 70$ for *P. vulgaris*), are all lower than those reported here. This is undoubtedly largely due to the extreme difficulty in counting the chromosomes of the *vulgaris-amara* group. Counts regarded as individually conclusive were obtained from only a small proportion of the localities examined in this work, though conclusive counts were obtained on each species other than *P. alpina* and clear cases of deviations from the numbers shown were extremely rare.

Baksay's² count on *P. amara* refers to a taxon not studied by me, but as her count was made on diakinesis, which I have found deceptive in that some chromosomes are not stainable until the very latest stages, the number could have been higher than she records. If some of the satellites recorded by Larsen³ in *P. comosa* were independent small chromosomes his plant could be a $2n = 34$ form. Wulff⁵, in recording $n = 24$ to 28 for *P. vulgaris*, spoke of difficulties in counting due to meiotic irregularities. Mattick's⁴ finding of roughly diploid chromosome numbers in some of her *P. vulgaris* is interesting, but could be due to confusion with the closely related and very variable *P. comosa*. However, more work on European *P. vulgaris* is clearly needed.

Meiotic irregularities have been reported by Hagerup⁸ and Wulff⁵ in *P. vulgaris* from Denmark and Schleswig Holstein. In the present work they were found to be common in *P. comosa*, but rare in other species. The usual irregularity is the presence of univalents, leading to irregular tetrads. In *P. comosa* the degree of irregularity of the tetrads varied from bud to bud in the same spike (from apparent normality to about 40 per cent of the tetrads abnormal), suggesting that irregularities occurred in response to less favourable weather conditions. Most irregularities in other species could also be attributed to abnormal conditions. It is possible that at times the chiasma frequency may be so far reduced that some potential bivalents are not joined (cf. Elliott⁹).

Variation in the number of chromosomes in pollen grains of *P. chamaebuxus* has been established⁷; but it is not known if this reflects variation in the somatic chromosome number or is an immediate result of irregularities of meiosis. No irregularities in the meiotic process have yet been observed in this species, and more work is required.

A full account of this work, including observations on some interspecific hybrids, is in preparation.

PSYCHOLOGY

The Relativity of 'Meaning'

DR. W. ROSS ASHBY's communication on this subject¹ is very interesting and may prove to have much technical value, provided that it is possible to achieve a closed system of the outputs with which the brain may respond to the incoming message. This is the crux of the whole question. It is assumed that useful closed formalisms for this purpose are possible. In point of fact, every formalism that we know is made to work by unformalized human adjustments. Without these, the formalism would become so complex that it would lose its value as a shorthand. It would be uneconomical in practice.

It is necessary, then, in setting up a particular formalism to accept the limitation imposed by the practical use of the system and the resources available to use it. Ultimately, this means computing fast enough at an acceptable cost. I have no doubt that there will be invented successful schemes with limited applicability to handle the problem of meaning in translation and other processes that connect messages with action, but no useful purpose will be served by claiming to formalize all the possibilities of human behaviour.

It is very interesting to see recognized in a technical communication that application of a message shows its meaning in the context of the particular occasion, seeing that it is now some time since Wittgenstein first emphasized this thought, and the essential informality of behaviour in responding to ordinary language.

W. H. WATSON

Department of Physics,
University of Toronto,
Toronto 5, Ontario.

¹ *Nature*, **187**, 532 (1960).

DR. W. ROSS ASHBY¹ has made the interesting assertion that the meaning of a message carrying information depends on the context of the message. Thus, if someone sends *A* of two possible telegrams, *A*, "How we wish you were here" and *B*, "The weather is fine", the meaning of the message is different from that of the same message chosen from three messages *A*, *B* and a third one, *C*, "Do come and join us". This may well be true in a coding

system as usable in mechanical information transfer, but it is not true of ordinary human assertions, messages and speech, except possibly in a few odd cases. If a radio message is sent, "The flowers are blooming", and it is the expected message instructing a submarine commander to release a torpedo, it is arbitrary that this particular sentence was pre-arranged as the message. It could have been a bell sounding, or a man blowing his nose that was the message. If I wish to convey the information that the cat is on the mat, in English, it is not arbitrary what message I use. As the corollary of this, it would be absurd to say that one of the possible meanings of the English sentence, "The flowers are blooming", is that it is an order to fire torpedos. It is similarly absurd to say, as Ashby does, that one of the possible meanings of "How we wish you were here" in English is "We wish to be cordial but do not require your company". The meaning of a simple assertion does not change when the speaker is a liar.

What does change according to the context is what it is possible to infer from the message, or in other words, its information content. Since, however, ordinary English meanings are determined by customary usage, and this particular usage is not at all necessary in constructing a means of communication, it is perfectly feasible, and simple even, to arrange a cipher where the significance of a symbol is altered according to its context among other symbols in the same cipher, as the figure 2 is of different significance in the figures 112 and 211. Thus, for constructing machines or other systems for conveying information by messages, it is possible, but not necessary, that the meaning of a message should depend on its context. It is a mistake to say that this holds for ordinary language.

J. WILLIAMSON

Department of Philosophy,
Birkbeck College,
London, W.C.1.

¹ Ashby, W. R., *Nature*, **187**, 532 (1960).

MR. WILLIAMSON points out that in most ordinary language the meaning of a sentence depends on its context only to a trifling or zero degree. Nevertheless, the recognition that the dependence is latent may be worth making. We all know how much Shannon and Wiener contributed by their recognition that the *quantity* of information in a message is a function both of it and of the unsent messages. They showed that a coherent theory can be developed only when the set of messages is regarded as a whole. It may be that a theory of meaning similarly must be based on consideration of the whole set. In such a theory, the sentence the meaning of which depends on context to only zero degree would be regarded as a special (though common) case, degenerate in the way that 'still air' corresponds to the wind that blows at 0 miles per hour.

W. ROSS ASHBY

Burden Neurological Institute,
Bristol.

DR. ROSS ASHBY¹ is right (defining "right" as "what I think the best people think" and "best" as "the class of people who think as I do") in his conclusions that no message has intrinsic meaning, and the meaning defined in terms of the set of messages from which it was taken (the sender's

meaning) is relatively unimportant. In most cases the message is not consciously composed by an intelligent sender; in many cases our messages arise from non-living matter. The important meaning is the recipient-meaning and this meaning is very personal to the individual recipient (be it man, dog or computer), will vary with instant of reception and will generally decay after reception. It may be defined as the multiplex of correlates stimulated in the recipient by the input message. Even the most intelligent recipient will "know" only in part what this multiplex is. Much of it will not be accessible to his awareness, let alone his analytical senses. Even if he did "know" it, he could not convey it with any absolute certainty to a third person, for the establishment of a common language is a statistical process with a finite residual error-probability even for the most elementary conceptions; and this indeterminacy of meaning applies equally to communications between intelligent beings and to the raw information gathered by the absorption of electromagnetic or acoustic radiation or of vapours from, or contact with, the recipient's environment.

From this we see that no "fact" can ever be "true" in any absolute sense, and the definitions in my first sentence are not flippancies. Nor can any symbolic logic be designed to be absolutely true. Any attempt to reduce "facts" to "atomic" constituents, absolutely transferable, is doomed to failure from the outset, whether the atoms are simple conceptions (which never are simple), or the smallest perceptible increment of intensity (of light or sound) in a particular resolution-cell (of colour, position on the retina, sound-pitch, etc.). For the cross-correlation of such in two recipients will never be more than asymptotic to completeness. Our ability to affect, by intercommunication, each others' actions, and store of correlation patterns determining future actions, will always be on a probabilistic basis. The message transcribed into the memory will sometimes be quite different from the sender's intention, and his-truth will generally differ from my-truth and your-truth.

When we see clearly that there are no intrinsic meanings in words, then we are able to discount such words as 'mind', 'spirit', 'soul', 'psyche', 'freewill', as simply widely used poetic descriptions of some aspect of brain-function and to explain such words as 'truth', 'goodness', 'morality' and 'beauty' in scientific terms, and the conflict with Christian belief is resolved². When we realize, with relief, that there is no intrinsic meaning in the whole, or any part, of the universe, we also see that the beauty of a universe governed by simple laws is no argument in favour of a creator. For the very existence of life (defined as a class of agglomerates of matter so formed as to take advantage, by prediction from stored information, of its environment to increase the probability of perpetuation of its own kind) is utterly dependent on the predictability of that environment. Were the universe not well ordered we could not be here; we can know no universes but beautiful ones, and as things we know not, do not exist, then all universes are inevitably beautiful.

G. F. CLARKE

Guided Weapons Department,
Royal Aircraft Establishment,
Farnborough,
Hants.

FORTHCOMING EVENTS

(Meetings marked with an asterisk * are open to the public)

Monday, November 14

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS AND COMMUNICATION SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "Tunnel-Diode Applications and Circuitry", opened by Dr. G. B. B. Chaplin and Dr. R. W. A. Searr.

ROYAL GEOGRAPHICAL SOCIETY (joint meeting with the ANGLO-SWISS SOCIETY, at 1 Kensington Gore, London, S.W.7), at 8.30 p.m.—Mr. Max Eisel: "The Ascent of Dhaulagiri".

Tuesday, November 15

INSTITUTE OF PHYSICS AND THE PHYSICAL SOCIETY, ELECTRONICS AND LOW TEMPERATURE GROUPS (at 47 Belgrave Square, London, S.W.1), at 10 a.m. and 2.15 p.m.—Meeting on "Electronic Devices at Helium Temperatures".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 1.15 p.m.—Dr. K. A. Kernach: "Fossils from Fissures".*

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 5 p.m.—Prof. J. Wyart (University of Paris): "Diffusion of Atoms (Na, K, Al, Si, O) in Felspars".* (First of two Special University Lectures in Crystallography. Further lecture on November 16.)

INSTITUTION OF ELECTRICAL ENGINEERS, MEASUREMENT AND CONTROL SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. T. Gluchoroff: "Discrete Analogue-Computer Compensation of Sampled-Data Control Systems".

UNIVERSITY COLLEGE (in the Anatomy Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. E. E. Evans: "Environment and Society in the Atlantic Fringe".* (Further lectures on November 17 and 18.)

UNIVERSITY COLLEGE (in the Physiology Theatre, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. J. H. Gaddum, F.R.S.: "The Pharmacological Analysis of Tissue Extracts".*

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. K. S. Kirby: "Nucleic Acids and Cancer".* (Eighth of the fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

ROYAL INSTITUTE OF CHEMISTRY (at Shell Mex House, Strand, London, W.C.2), at 6.30 p.m.—Annual General Meeting.

Wednesday, November 16

INSTITUTE OF METAL FINISHING (in the Recital Room of the Royal Festival Hall, London, S.E.1), at 9.30 a.m.—Symposium on "Nickel-Chromium Plating".

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 2 p.m.—Dr. A. L. Greenbaum: "Fat Metabolism".*

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, London, S.W.7), at 5 p.m.—Scientific Papers.

UNIVERSITY OF LONDON (at Birkbeck College, Malet Street, London, W.C.1), at 5 p.m.—Prof. J. Wyart: "Hydrothermal Synthesis and the Problem of Granitization".*

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.15 p.m.—Prof. M. G. Kendall: "The Natural Law in the Social Sciences" (Inaugural Address).

INSTITUTION OF ELECTRICAL ENGINEERS, SUPPLY SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. E. H. Cox and Mr. R. E. Martin: "Radiocommunication in the Power Industry".

UNIVERSITY OF LONDON (in the Chemistry Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. R. J. Forbes (University of Amsterdam): "The History of the Petroleum Industry: Processing and Products during the Past Fifty Centuries".* (First of three Special University Lectures in the History and Philosophy of Science. Further lectures on November 17 and 18.)

BRITISH INSTITUTION OF RADIO ENGINEERS, COMPUTER GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Lt.-Col. I. W. Peck: "Digital Computing Elements for Instructional Use".

Thursday, November 17

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Special General Meeting, followed by Dr. G. Herzberg, F.R.S.: "The Spectra and Structures of Free Methyl and Free Methylene" (The Bakerian Lecture).

INSTITUTION OF MINING AND METALLURGY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. Kun Li, Mr. R. W. Livingston and Mr. L. K. Lemke: "Flotation Conditioning of Iron Ore with Petroleum Sulphonate"; Mr. G. J. Brittingham: "Rehabilitation of Chang Hang Copper Smelter, South Korea".

LONDON MATHEMATICAL SOCIETY (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Annual General Meeting. Prof. G. Kreisel: "Recent Work on the Foundations of Analysis".

UNIVERSITY OF LONDON (in the Physiology Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Prof. R. A. Morton: "Ubiquinones and Related Substances—Nature and Biological Functions".* (Further lecture on November 24.)

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. J. C. Kendrew: "The Structure of Proteins".* (Ninth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

SOCIETY OF CHEMICAL INDUSTRY, ROAD AND BUILDING MATERIALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Dr. L. J. Wood: "The Constitution and Properties of Tars and Tar-Polymer Mixtures".

Friday, November 18

BIOCHEMICAL SOCIETY (at the Middlesex Hospital Medical School, Mortimer Street, London, W.1), at 10 a.m.—Colloquium on "Histochimistry". Afternoon session—Original communications on histochimistry and other subjects.

INSTITUTE OF NAVIGATION (joint meeting with the BRITISH INTERPLANETARY SOCIETY, at the Royal Geographical Society, 1 Kensington Gore, London, S.W.7), at 10 a.m.—Symposium on "Navigation for the Early Exploration of the Moon".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. M. Westergaard (Copenhagen): "Some Fundamental Concepts and Problems in Molecular Genetics".* (Further lectures on November 22 and 23.)

SOCIETY OF CHEMICAL INDUSTRY, FINE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. J. F. Danielli: "Physicochemical Aspects of Chemotherapy".

ROYAL INSTITUTE (at 21 Albemarle Street, London, W.1), at 9 p.m.—Mr. D. E. Broadbent: "The Perception of Speech".

Saturday, November 19

BRITISH INTERPLANETARY SOCIETY (in the Tudor Room, Caxton Hall, London, S.W.1), at 6 p.m.—Mr. D. Andrews: "British Participation in Space Research".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (with a degree and/or corporate membership of a professional institution, and preferably the ability to offer electrical measurements as a specialist subject) in ELECTRICAL ENGINEERING at Brighton Technical College, to teach to final degree and diploma standard—The Director of Education, 54 Old Steine, Brighton, Sussex (November 19).

LECTURER (with a good honours degree in pharmacology or physiology, or a qualification in medicine, and a postgraduate qualification in pharmacology) in THE DEPARTMENT OF PHARMACOLOGY—The Registrar, King's College (University of London), Strand, London, W.C.2 (November 22).

SENIOR LECTURER (preferably with a medical qualification) in THE DEPARTMENT OF EXPERIMENTAL PATHOLOGY AND CANCER RESEARCH—The Registrar, The University, Leeds (November 22).

LECTURER (specially interested and qualified in the fields of petrology and mineralogy) in GEOLOGY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, November 25).

LECTURER or ASSISTANT LECTURER in APPLIED MATHEMATICS—The Secretary, The University, Northcote House, Queen's Drive, Exeter (November 26).

ASSISTANT LECTURER (preferably qualified in physical chemistry) in CHEMISTRY—The Registrar, The University, Leicester (November 30).

ENTOMOLOGIST, Scientific Officer or Senior Scientific Officer grade (with a good honours degree), to study the effect of insecticides on insect populations—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (November 30).

LECTURER (with a good honours degree or equivalent and preferably teaching experience) in THEORETICAL PHYSICS; and a LECTURER (with a good honours degree or equivalent and preferably teaching experience) in PHYSICS at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, November 30).

READER IN ANALYTICAL AND INORGANIC CHEMISTRY; and a LECTURER or ASSISTANT LECTURER in INORGANIC CHEMISTRY—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (November 30).

SCIENTIFIC OFFICER (with a first- or second-class honours degree in mathematics with statistics, or a diploma in statistics) in THE STATISTICS SECTION, for duties mainly concerned with the design and analysis of field experiments—The Secretary, The Macaulay Institute for Soil Research, Craigiebuckler, Aberdeen (November 30).

BIOLOGIST (with Ph.D., M.Sc., or B.Sc. in wildlife management or zoology, with experience in independent water-fowl research) in THE WILDLIFE BRANCH, Department of Internal Affairs, Wellington, New Zealand, to carry out life-history studies of mallard and native grey duck populations or such other projects as may be assigned—The High Commissioner for New Zealand, 415 Strand, London, W.C.2 (December 1).

PROFESSOR OF AGRICULTURE AND DIRECTOR OF THE COLLEGE FARM—The Secretary and Registrar, University College of North Wales, Bangor, North Wales (December 1).

BEYER CHAIR OF APPLIED MATHEMATICS—The Registrar, The University, Manchester 13 (December 3).

LECTURER IN THE DEPARTMENT OF CLASSICAL ARCHEOLOGY—The Secretary, The University, Edinburgh (December 5).

HEAD OF THE DEPARTMENT OF VIROLOGY, for duties which will include responsibility for the development of the Department for the study of animal viruses in close collaboration with the Departments of Pathology, Bacteriology and Biochemistry—The Secretary, Field Station, Agricultural Research Council, Compton, near Newbury, Berkshire (December 15).

LECTURER OR ASSISTANT LECTURER IN PHYSICS at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 15).

LECTURER (specialized, or prepared to specialize in the pre-history of South-East Asia and/or Oceania, and able to teach elementary physical anthropology) in **ANTHROPOLOGY** at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 15).

LECTURER (with at least a first-class honours degree in chemical engineering) in **CHEMICAL ENGINEERING** at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 19).

SENIOR LECTURER IN BOTANY and a **LECTURER IN BOTANY** at the University of Adelaide, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia, December 20).

SENIOR TUTORS (2) IN PURE MATHEMATICS at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 20).

SENIOR RESEARCH FELLOW OR A RESEARCH FELLOW IN THE DEPARTMENT OF NUCLEAR PHYSICS, Research School of Physical Sciences, Australian National University, to work either in the field of nuclear spectroscopy or on photonuclear problems—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 30).

CHAIR OF ZOOLOGY in the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 31).

TURNER AND NEWALL FELLOW (preferably under 28 years of age) at Newcastle or Durham, for research in Engineering, Inorganic Chemistry or Physics, or an allied science—The Registrar, University Office, 46 North Bailey, Durham (January 31).

IMPERIAL CHEMICAL INDUSTRIES LIMITED RESEARCH FELLOWS IN BACTERIOLOGY, BIOCHEMISTRY, BIOMOLECULAR STRUCTURE, BOTANY (PLANT BIOCHEMISTRY AND BIOPHYSICS), CHEMICAL ENGINEERING, CHEMISTRY, CHEMISTRY OF LEATHER MANUFACTURE, CHEMOTHERAPY, COLOUR CHEMISTRY AND DYEING, ENGINEERING (CIVIL, ELECTRICAL AND MECHANICAL), FUEL AND REFRATORIES, GEOLOGY (INCLUDING GEOCHEMISTRY), METALLURGY, MINING (SELECTIVE FLOTATION AND GEOPHYSICAL SURVEYING), PHARMACOLOGY, PHYSICS, PHYSIOLOGY OR TEXTILE INDUSTRIES (CHEMISTRY OF HIGH POLYMERS (KERATIN AND MAN-MADE FIBRES), TEXTILE TECHNOLOGY AND TEXTILE ENGINEERING)—The Registrar, The University, Leeds 2 (February 17).

ANALYTICAL CHEMIST (with an honours degree in chemistry or Associate Member of the Royal Institute of Chemistry, and preferably postgraduate experience in a public analyst's laboratory or veterinary research establishment), at the Veterinary Research Laboratories, near Nairobi, Kenya, to analyse animal food-stuffs for legislation purposes and carry out research in nutrition—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BCD.67/7017.

ASSISTANT LECTURER IN PHYSIOLOGY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

ASSISTANT VIROLOGIST (with previous experience in virological techniques) to undertake research on rubella and molluscum contagiosum, with particular reference to the isolation of their causal agents—Head of the Virology Department, The Lister Institute, London, S.W.1.

PRINCIPAL LECTURER (qualified to teach to final degree or diploma in technology standard) in the **DEPARTMENT OF BIOLOGICAL SCIENCES**—The Registrar, Bradford Institute of Technology, Bradford 7.

RESEARCH ASSISTANT (with a science degree in physiology, biochemistry or a cognate subject, and preferably experience in pharmacological or biochemical techniques) to the **PROFESSOR OF PHARMACOLOGY**, for work related to the assay of chemical transmitters in tissues and body fluids—Prof. G. Brownlee, Department of Pharmacology, King's College (University of London), Strand, London, W.C.2.

SUPERINTENDENT OF CHILDREN'S ZOOS in the L.C.C. Parks Department (preferably zoologist with some years practical experience)—Chief Officer, Parks Department (A.1/N/2736/11), County Hall, London, S.E.1.

Ministry of Housing and Local Government. Smoke Control (England and Wales): Summary of Programme submitted by Local Authorities for the Establishment of Smoke Control Areas. Pp. 19. (Cmd. 1113.) (London: H.M. Stationery Office, 1960.) 3s. net. [48]

CO-OPERATION BETWEEN SCHOOLS AND UNIVERSITIES
IN EDUCATIONAL DEVELOPMENTS

IN recent months the adequacy of university teaching both in chemistry and physics has been challenged by competent authorities, and some suggestions made that could make more time available for critical thought and for the more general education for which there have also been widespread and authoritative calls. The recent report of the Advisory Council on Scientific Policy (see *Nature*, November 5, p. 435) was mainly concerned with a review, undertaken at the specific request of the Minister for Science, of the balance of scientific effort in Britain, but the report also contains an important section on education in science. This likewise arose out of a request from the Minister for Science to consider the implications for science of the Crowther Report, and while the Council welcomed many of the recommendations in the Crowther Report, on questions of curricula, supply of teachers, and the raising of the school-leaving age in relation to the development of the proposed county colleges and the training of technicians, the experience of some of its members is at variance with the Crowther Committee's recommendations.

On the supply of teachers, the Advisory Council for Scientific Policy observes that on the figures at present available, the demand for teachers caused by reducing the size of classes is much greater than that consequent on raising the school-leaving age, and in either event the number of science and mathematics graduates needed for school teaching does not greatly exceed the number likely to be obtainable on the Council's present forecasts of scientific man-power. On the other hand, it points out that there may be difficulty in finding sufficient university teachers of quality in certain subjects, notably mathematics, to cope with the large increase in university population now proposed. Adequate provision in this respect is absolutely essential in universities if they are to produce the graduates required. Equally important, the Advisory Council points out that the desirability or otherwise of concentrating resources on raising the school-leaving age is intimately bound up with the needs of education for industry, and especially with the need for technicians. These will be required in large numbers if we are to get the full benefit from the increased numbers of scientists and engineers we are now producing, and it could be urged that it is the more important to increase the numbers of technicians quickly so as to secure the most effective use of the present limited numbers of scientists and technologists in industry, in Government service and in the universities. This point is borne out by the recent report from the Civil Service Commissioners for the year ending March 31, 1960; and as many of these technicians, and still more of the craftsmen

on whom industry must depend, come from those who now leave school at fifteen, the Council suggests that a major extension of part-time education to the age of eighteen is more urgent than the raising of the school-leaving age.

There is a note of confidence and authority about the Advisory Council's whole report that should ensure that these suggestions are duly heeded, though it is surprising to find that the industrial members of the Council attach such value to evening classes as a component of existing part-time education. The Advisory Council emphasizes the importance of the development of county colleges, which, with the technical colleges, would be the main instruments of the part-time education it recommends, and it urges that this development should be more rapid than is envisaged in the Crowther Report. The system of day-release, however, is not mentioned by the Advisory Council; but in addressing the British Association for Commercial and Industrial Education at Cambridge on September 23, the Minister of Labour, Mr. John Hare, gave industry a clear and emphatic warning of its own responsibilities for industrial training and the urgency of a problem to which, in spite of the establishment of the Industrial Training Council, many firms are giving insufficient attention.

It is, however, on the question of the school science curriculum and specialization in schools that the Advisory Council is most forthright and authoritative. It has no doubt that school science curricula need a thorough re-examination. They tend at present to be unimaginative and to be overloaded with factual material, partly because new material is added without removing the old. It was suggested to the Council that up to 20-25 per cent of the content of the curricula in physics, chemistry and biology could be removed with advantage rather than detriment, and in particular a new approach is needed to the teaching of biology. The Advisory Council suggests it should be treated as a comprehensive discipline in its own right, with a bearing on the teaching of geology and geography, and so taught, with much more field-work than customary at present, it should be an integral part of the junior- and middle-school curriculum for all pupils.

The Advisory Council was, of course, fully aware of the extensive studies on the content of school science courses in the United States which the National Science Foundation has stimulated, and it understands that the Ministry of Education is already in touch with the Foundation. Science teachers at all levels could well support the Advisory Council in seeing that the closest possible contact is maintained, and in this connexion the possibilities offered by

sound broadcasting and television should be fully and authoritatively explored. To these possibilities the Organization for European Economic Co-operation has already directed attention in its report, "Teaching through Television".

The Advisory Council also considers that specialization in schools has gone too far, and that here is to be found the origin of the so-called 'gulf' between scientists and non-scientists. It deplores the segregation of children in the middle school into groups according to the subjects they are to study in the sixth form, and believes that with the revision of science and mathematics curricula all middle school pupils should be able to study science without making undue inroads into other subjects. In its opinion, all pupils in the middle school should have the same general education, in which science should play its full part. It urges, in fact, exactly what Sir Cyril Hinshelwood suggested in addressing the Manchester Literary and Philosophical Society; it rejects the idea that a few periods of general studies suffice as a leavening for the 'science sixth' or a few periods of general science for the others, and believes that curricula can be modified so that those who are primarily interested in science can continue a serious study of some other subjects and *vice versa*.

Beyond this, there are signs of over-specialization in science itself in the sixth form, and as things stand at present the Advisory Council agrees with the Crowther Committee's view that two science subjects may be all that a student should take at the Advanced Level of the General Certificate of Education examination. Reduction of the factual knowledge demanded in individual subjects and revision of curricula in the manner already indicated would, however, permit a corresponding increase in the breadth of sixth-form education, and the Council believes this should be done. Further, it stresses the urgent need for schools and universities to get together to devise some method of awarding scholarships which will avoid the over-specialization and disproportionate effect on school curricula which at present arises from college scholarship requirements at Oxford and Cambridge, and it points out that, in view of the present considerable overlap between what a student is taught in science in his first year at the university and what he has already learned in his last year at school, many professors would welcome a lower level of factual knowledge of their own subject in pupils entering the university if it were combined with a broader general education.

While the Crowther Committee endorsed the principle of specialization, or study in depth, it did not necessarily support all existing practice, and in fact it pointed out that syllabuses in science need reconsidering both subject by subject and together as the specialist curriculum of the science sixth. The Report, moreover, included some valuable suggestions for controlling premature specialization, and these have been welcomed by many headmasters. The present system of work has, however, since been challenged both in a report issued by the University of Oxford Department of Education based on an inquiry

financed by the Gulbenkian Foundation into "Arts and Science Sides in the Sixth Form"*, and also in one issued by the Secondary School Examination Council entitled "The General Certificate of Education and Sixth Form Studies"†.

The Oxford report maintains that the present degree of specialization is greater than the Crowther Committee believed: it had evidence that nine-tenths of the working time of a sixth former is concentrated on either arts or sciences, and that in practice four-fifths of all pupils have to make an effective decision at 14-15 between a scientific and a literary education. Further, this degree of specialization is not found in any comparable country, and has arisen from local historical causes and not from educational principles. The Crowther Report itself pointed out that university entrance requirements should not determine the nature of sixth-form work, but at present they do; and the Secondary School Examination Council's report criticizes this university pressure even more strongly. In fact, it believes the pressure to show results in terms of examination achievement for such purposes as admission to a university has become so intense that specialization is carried to a point at which general education is in jeopardy.

The main source of pressure is, in fact, the keen and growing competition to enter a university, and it is estimated that by 1965 the number of candidates for the Advanced Level General Certificate of Education examination will have risen from 83,000 in 1959 to 150,000, although the planned expansion of university places in England and Wales for full-time courses is only from 22,000 to 32,000. The universities certainly need an examination which does not simply measure a pupil's achievement at school, but also offers some guidance on a pupil's potential for a university course, and especially for an honours course; and the Advisory Council, besides recommending the revision of Advanced Level syllabuses to reduce their factual and memory content, suggests that if a revised examination is introduced the universities might make it optional rather than obligatory to have three passes at Advanced Level. This pressure may well be the more serious if, as Prof. R. A. C. Oliver, for example, believes, the number of sixth formers not going on to universities greatly increases. Prof. Oliver himself believes that the present Advanced Level examination is detrimental to the university entrant, because it requires him to present his credentials exclusively in terms of his two or three specialized subjects. The whole implication of Dr. James Taylor's presidential address to Section B (Chemistry) at the Cardiff meeting of the British Association supports the argument of Prof. Oliver and those with him. The increasing scope of the scientist's work in industry means not simply that chemistry alone is not enough but also that an adequate broad general education is essential; and time must be found for this, both in school and

* Arts and Science Sides in the Sixth Forms. (Oxford Univ. Department of Education, 1960.) 2s. 6d.

† Examinations in Secondary Schools. Third Report. The General Certificate of Education and Sixth Form Studies. (London: H.M.S.O., 1960.) 2s. 6d.

in university, if men and women competent to meet the needs of industry itself are to be provided. Moreover, as already noted, it is not simply scientists and technologists who are needed, but also, and in even greater numbers, technicians and craftsmen, and one consequence of the present educational system is the tendency to under-value craftsmanship, or even, as Sir Cyril Hinshelwood has emphasized, to divert some with potentially first-rate manual skill into becoming second- or third-rate intellectual workers. Manual skill, Sir Cyril insisted, is in many ways as worthy of respect as mental agility. Technology involves both, and is not to be thought less liberal than fundamental science if approached in a liberal spirit, any more than the sciences are to be deemed less liberal than the arts.

In saying this, Sir Cyril had launched a devastating attack on the artificial barriers often set up between the arts and the sciences, urging that in all the arts, and in all the sciences, full satisfaction is only reached by the practice of creative effort, realized through the medium of a technique, painfully and elaborately acquired and involving natural aptitude. No educational system can be regarded as satisfactory which does not permit due account to be taken of such natural aptitudes, but the whole tenor of the address which Sir Cyril Hinshelwood gave to the Manchester Literary and Philosophical Society implies not simply the basic importance of a broad general education but also the practicability of such an education being given side by side to those seeking to specialize in the arts and in the sciences up to an advanced stage, provided the extent to which the arts and the sciences make similar demands on observation and experiment, imagination and creative powers is properly recognized. It is a matter for both school and university, and a solution will not be found except by close co-operation between them.

Unfortunately, this did not appear to be recognized adequately in the discussion on the education of scientists at a meeting of Section L (Education) at the British Association meeting in Cardiff, except possibly in Sir Patrick Linstead's address. Prof. M. W. Thring, it is true, challenged the idea that the humanities are superior to pure science, or the latter to technology, and maintained that the broadening of education by informal methods is a vital part of the training a university should give. He directed attention, moreover, to the influence which the school teacher has on the choice of a career, and the consequent handicap under which technology is placed since so few of those trained in technology teach in the schools. This is, in fact, a particular aspect of a problem on which a study group set up in 1958 by the Nottingham County Education Committee and the East Midlands region of the Institute of Personnel Management has commented strongly: the group was seriously perturbed by the danger of 'remoteness' of the student teacher and his/her tutor from the general industrial life of the community.

Prof. Thring was particularly concerned as to how we could show our ablest schoolboys that applied science is worthy of their talents, and could offer

them a fascinating and satisfying career. This problem is not solved by the establishment of more colleges of technology, and it was not really considered by Dr. J. S. Tait in his paper, although he recognized the value of the time which the students are required to spend in industry and, like Prof. Thring, he referred to the importance of some research in technology. Dr. Tait's reference to the fostering of interest in the humanities was rather superficial, but Sir Patrick Linstead gave a preliminary account of the inquiry conducted by a special committee of the British Association, with the aid of a grant from the Leverhulme Trust, into the means of broadening the education of the graduate scientist, and this inquiry covers the whole range of education from school to university.

Both schools and universities have important but different formal parts to play, but Sir Patrick did not refer to co-operation between them or the way in which the adverse effect of university pressure on the schools could be reduced. More time for minority subjects in the sixth forms was recognized as one essential step, and once again the need for some reduction in the factual content of university courses and deflexion towards the study of general principles is recognized. Other suggestions at the university-level included greater attention to those non-scientific subjects which arise naturally out of the special subjects, such as the history of scientific thought and method and the use of English; the provision of a wide range of cultural events, on an organized but not compulsory basis; and the generous provision of amenities, such as libraries, halls of residence and beautiful surroundings.

The importance of early and decisive co-operation between the schools and the universities can scarcely be over-stressed, and there is no more important recommendation in the report of the Advisory Council on Scientific Policy than the one to that end. It is essential that the full implications of such a step should be faced, and appropriate measures devised to avoid the detrimental effects of the present system of awarding scholarships before and not after the present plans for university expansion are worked out in detail. It bears closely both on the question of general education and the quality of the graduates in science and technology which we produce, and on the use we make of them. In his recent book on American education, "The Child, the Parent and the State"*[†], Dr. J. B. Conant emphasized the way this question of effective use of the trained scientist or technologist determines the answer to the question of how many scientists and technologists we should be training, though it is only fair to recognize that the Crowther Committee also referred to it, particularly in respect of the use of sixth-form teachers.

Such questions are the more important in view of the mounting cost of education, and it may well be doubted whether all those who are advocating university expansion so strongly appreciate how much

* *The Child, the Parent and the State*. By Dr. James Bryant Conant. Pp. vi+211. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1959.) 28s. net.

it will cost and what is involved in willing the means. When Dr. Conant writes, of the American scene, that a climate of opinion must be created which brings forth in each young person a strong desire to do his or her best in school, he refers to a condition no less essential in Britain, as well as to what could well be another compelling reason for reform of curricula. He is equally aware of the importance of the technician, and, like Sir Cyril Hinshelwood, stresses the vital need for seeing that full opportunity is given for the expression of manual skills with intellectual skills in a whole spectrum of occupations.

Here, and when he refers to the need for an enlightened, public-spirited and stable electorate for fostering the development of a critical judgment regarding those who handle affairs of government, Dr. Conant touches on matters which need serious consideration in the planning of our educational institutions at the school- and the university-level alike. Indeed, he goes so far as to suggest that how to develop intelligent discrimination in future voters is one of the most challenging educational questions facing those responsible for social studies in schools. Be that as it may, Dr. Conant indicates a further decisive reason for a broad general education both in school and in university; but it is difficult to imagine a more authoritative lead in that respect or firmer warning as to the dangers and waste which continued excessive specialization in schools is liable to cause than that which has now come from the Advisory Council on Scientific Policy. The Minister for Science can scarcely do less than ensure that the Minister of Education takes action on his side, and that the University Grants Committee takes any initiative required. There is indeed ample evidence that industry, the universities and other potential employers attach greater importance to this question of general education and look with disfavour on excessive and premature specialization. This, as the Crowther Committee recognized, is likely to be the decisive factor in leading schools and pupils to take seriously the work done in minority time; but this by itself is not enough. It is to be hoped that the Advisory Council on Scientific Policy's recommendations may stimulate the coherent and properly phased programme of development, not simply for the schools but also for the universities, that is essential if educational expansion is to be adequate in scope and not to entail waste of precious resources.

THE COMPETITION FOR RURAL LAND

Agriculture and Urban Growth

A Study of the Competition for Rural Land. By Dr. G. P. Wibberley. Pp. 240+8 plates. (London: Michael Joseph, Ltd., 1959.) 21s. net.

FOR each head of population the land surface of England and Wales represents less than 0.8 acre—land of all sorts and for all purposes—against a world average of more than 12 acres. The figure is increased

only to 1.1 if Scotland is included and Britain considered as a whole. Not only is the population in Britain continuing to increase by about 200,000 a year but also our standard of living is rising, and the movement is constantly to the towns. Back-to-back houses in our industrial towns have become almost a thing of the past: the demand is for a more spacious layout of homes. As we approach the ideal, questionable though it may be, of one car per family, the demand for bigger and better roads becomes more insistent. There is the growing clamour for recreational areas: the desire to get away from the noise and congestion of the city—with a consequent invasion of the countryside, which may easily destroy the very qualities that render it attractive. At the same time there is the growing realization of the need to preserve some rural areas inviolate if the native fauna and flora of Britain are to survive, hence the work of the Nature Conservancy and the establishment of a varied range of Nature reserves.

It would seem obvious that the whole cake is so small that few demands on it can be satisfied in full, and that the only solution is an overall town and country planning. This indeed was the reason for the establishment of a Ministry of Town and Country Planning in 1943, for the Town and Country Planning Act of 1947, and for the Acts which have followed. Despite the laudable objectives, it has proved very difficult to get a calm, objective view of land planning; to some the very word is anathema, and arguments between the exponents of this policy or that are very liable to induce heat. It is precisely because Dr. Wibberley's book is a calm assessment of the facts, involving a very considerable amount of research by his team (especially R. H. Best and J. T. Ward, who might almost be named as joint authors) and himself at Wye College, that it is both a valuable and an opportune contribution. He has been accused by some as a 'master of brinkmanship'; in reality that is praise indeed, for he brings his readers to the brink where they can see the whole position. Which way they plunge is then their decision, and it is interesting to note how the exponents of most diverse views are finding ammunition in Wibberley's figures.

The expansion of towns into the country and the consequent loss of rural land is inevitable, but the rate of loss is important. The only reasonably complete official statistics of land use that we have in Britain are those collected by the Ministry of Agriculture, based on the returns made every June 4 by holders of agricultural land exceeding one acre in extent. As the years have passed the returns have become steadily more complete and more accurate. Apart from the difficulty of definition, there have been no comparable statistics of urban land. The area of 'urban land' has been ascertained by subtracting rural land, for which returns exist, from total area. Thus, for obvious reasons, the loss of agricultural land during 1900–1950 is more likely of the order of 2,250,000 acres than the 1,130,000 acres which official figures suggest (p. 58). The only direct measure of 'urban land' is that carried out by the Land Utilisation Survey of Britain during 1931–33, when the use of every piece of land was recorded on 6-in. maps. The accuracy of the Survey's figures is only limited by the scale on which the calculations were made—on the published one-inch maps—since the question of definition does not arise. What was, or was not, included in the various categories can at once be seen

from the published maps; if necessary the original 6-in. maps can be consulted. Wibberley expresses some surprise that from other evidence he finds these figures reasonably correct! Such is the strict discipline of the map, they could not be otherwise.

In general Wibberley accepts the estimates that "new urban developments and special uses are likely to require between 500,000 and 700,000 acres . . . mainly on the better farmlands of the lowlands", before 1971 (p. 58) and he is concerned with the replacement of agricultural production thus lost. He writes as an economist, and although he finds the value added by the land alone in Britain—the input-output ratio—is only of the order of £4 per acre per annum, and would seem to suggest that farming as a whole is scarcely worth while, he has some interesting calculations. If land is worth only £30 an acre and is devastated by mineral working, any expenditure in excess of £30 an acre in restoration is not economically justified—so runs the old argument which conveniently ignores the lessons of two world wars. It is certainly an advance when Wibberley argues that a capital expenditure of up to £165 in 'general intensification of agriculture' (1955–56 values) for each acre lost to building is justified on economic grounds.

Undoubtedly, the real value of the book lies in the ammunition provided by an economist in favour of the conservation of the resources of the better types of land in the lowlands rather than in the attempt to replace acreage lost in the lowlands by heavy expenditure in the highlands. L. DUDLEY STAMP

CUSTOM AND MYTH

Folkways

A Study of the Sociological Importance of Usages, Manners, Customs, Mores, and Morals. By Prof. William Graham Sumner. Pp. vii + 692. (New York: Dover Publications, Inc.; London: Constable and Co., Ltd., 1959.) 2.49 dollars; 20s.

IT is not altogether easy to understand why this book has been reprinted. First published in 1907, it became a highly influential work in the United States and the basis of the author's "Science and Society" which, written with the help of A. G. Keller, did not appear until much later.

Prof. Sumner had a varied career. Educated both in the United States and in Europe, he was at one time an episcopal clergyman and then was appointed professor of political and social science at Yale. He became interested in the theories of Spencer and Lippert, and came to believe that what he called 'mores' and 'folkways' had had a far greater influence than had hitherto been believed. By 'mores' he meant that vast system of usages which cover the whole of life, containing within themselves their own justification of tradition and approved by mystic sanction, thus developing into principles of truth and right. They defined the limits which made anything 'right': they covered manners with a mantle of current custom. It is thus that the folkways arise and are gradually converted into the mores.

In developing his theories and illustrating his thesis, Sumner was making a systematic study of various anthropological and sociological records, and this book is in essence a collection of his notes and

memoranda which were meant to be incorporated later into a more ambitious work. Strongly influenced by Darwinian teaching and the doctrines of *laissez-faire*, Sumner was a powerful exponent of individual effort, and he regarded all such ideas as those inherent in liberal socialism as an interference with natural laws. To Sumner the most important factors in the science of society are the folkways, which control both individual and social undertakings and nourish philosophical ideas generally. He does not consider them organic or material. Rather they belong to a super-organic system of relations, conventions and institutional arrangements.

As a work of interest to the historian of sociological research the book has long been esteemed in the United States, but its lack of sustained treatment and the date at which it appeared have now considerably lessened its value to the practical sociologist. E. J. DINGWALL

THEORY OF ELECTRIC CIRCUITS

Electric Circuit Theory

By Dr. F. A. Benson and Dr. D. Harrison. Pp. viii + 371. (London: Edward Arnold (Publishers), Ltd., 1959.) 30s. net.

THIS book will be welcomed by students of all colleges having a syllabus in electric circuit theory corresponding closely to that of the University of Sheffield, for here will be found all the material necessary for their examinations together with an adequate number of numerical problems and answers.

The authors cover d.c. and a.c. circuits, with a collection of useful network theorems, transformers, rotating machine circuits and thermionic valve circuits; and claim that their book is one of the few that covers light-current and heavy-current circuit applications in one volume. The space devoted to light-current applications is, however, very much greater than that allowed for the heavy-current problems, but in spite of this all reference to transistors has been omitted. The authors justify this on the grounds of the necessity to keep the book to a reasonable size, but to many readers it would have appeared preferable to omit some of the more advanced material to make room for at least an outline of transistor theory.

The book, although well written, is curiously uneven. No doubt this arises from the authors' efforts to base parts of the work on the standard required for first-year students and part on the standard for second-year students. This variation of standard is particularly evident in the circuit theorems, some of which are proved and others stated without proof. Yet by the end of the second year all students should be able to prove all the circuit theorems of which they make use. Thus, no proof is given that an active four-terminal network may have four independent parameters while a passive four-terminal network has only three, but the authors find space to give two proofs of the star-delta transformation.

There are a number of minor imperfections in the work, which are little likely to worry the average student, but could well be amended in a future edition. It would be wearisome to list all these, but

a few can be mentioned. The reference to super-conduction should either be omitted or made more accurate, even at the expense of a few more lines of description. Resistance alloys should be described by composition rather than by trade names. Impedances should not be described as vectors, and the special interpretation of the meaning of vectors when applied to sinusoidally varying quantities should be stressed more heavily.

Students usually have considerable difficulty in dealing with the sign in problems involving mutual inductance. The treatment here is somewhat perfunctory, and an expansion together with a diagram showing clearly the direction of winding of coils, the direction of currents and of voltages, would be of great assistance to them.

The setting of the type is generally good and only a few errors, none of great moment, were observed. There is, however, an excessive use of the solidus in the equations throughout the book, and this makes reading difficult.

A. H. M. ARNOLD

SCIENCE AND LIBERAL EDUCATION

Science and Liberal Education

By Dr. Bentley Glass. (Davis Washington Mitchell Lectures-Tulane University.) Pp. x+115. (Baton Rouge: Louisiana State University Press, 1959.) 3 dollars.

THIS book is based on the Davis Washington Mitchell Lectures given by Bentley Glass at Tulane University. Of the three lectures, one only, the second, deals with the subject the title of which is given above. Prof. Glass's primary research and teaching interests are concerned with genetics and especially with the influence of radiation on human heredity. In this connexion he serves as an adviser to the Atomic Energy Commission and as a member of the National Academy of Science's Committee on the Genetic Effects of Atomic Radiation. He is well known in the United States for his ability to interpret to the public significant aspects of genetic research.

His first lecture concerns genetics in the service of man. Prof. Glass's style is popular in the best sense of the word—he does not sacrifice the dignity and scholarship of the science for an easy, superficial appeal. The lecture is devoted to the genetics of plants in relation to their food value and the genetics of animals and man in relation to disease. After touching on the effects of radiation on mutation-rates, Prof. Glass considers the future of the human race in relation to population control and limitation, and he stresses the difficulties rather than the solutions of the matter.

His essay on liberal education in the scientific age is worth expansion into a whole book. It may be summarized in his own words: "Science, in ever greater measure, must permeate the study and teaching of each of the arts, humanities, and studies. These, on their side, must mollify, enrich and protect the sciences". This may appear to be trite, because it is so often said by educationists to-day; but, in an engaging manner, Prof. Glass is able to add some new and interesting ideas to this important and topical problem.

The third and last essay, which deals with Darwinian evolution and human values, is equally

brilliant. There is a short, critical review of the present position of Darwinism in the larger sphere of evolution. There is much in common in these essays with Prof. Peter Medawar's Reith Lectures, and in the work here considered it is interesting to observe the different approach with its piquant American flavour.

W. L. SUMNER

THE AGEING INDIVIDUAL

Handbook of Aging and the Individual

Psychological and Biological Aspects. Edited by James E. Birren. Pp. xii+939. (Chicago: University of Chicago Press; London: Cambridge University Press, 1959.) 12.50 dollars; 100s.

THIS enormous volume is symptomatic of the growing interest in and research on the topic of ageing in the United States. The first of three handbooks aiming at summarizing all that is known to-day about the problems of human ageing, the present work, edited by Dr. James E. Birren of the National Institute of Mental Health, Maryland, is concerned with the psychological and biological problems of the ageing individual. It is to be followed by two volumes on social gerontology.

Primarily a work of reference, and intended as a definitive secondary source of data, the handbook succeeds in compressing a vast amount of information on almost every conceivable aspect of human ageing—biological, morphological, neurophysiological, neurochemical, genetic, pathological, environmental and psychological (with perhaps a major emphasis on the psychological). The editing has been well done: there is no undue overlapping between the contributions of the thirty authors, and the standard is in general first rate. Although there is inevitably a good deal of padding in the form of general background material not specifically concerned with ageing, this can perhaps be justified in a work designed to be of use to workers trained in quite a variety of different disciplines.

In two respects the book is more than compilation, and is likely to be of first-hand interest to gerontologists. First, it discusses perhaps more thoroughly than has been done before the fundamental principles and methodology of the study of ageing. Secondly, by reason of the very completeness of its coverage, it points to gaps in knowledge and suggests areas urgently needing more research. The book, in any event in parts, has a stimulating and suggestive quality that is not too common in synthetic productions of this kind. No doubt the editor, Dr. J. E. Birren, is largely responsible for this, and his own contribution on "The Principles of Research on Aging" with which the book opens is a particularly valuable one, discussing both the special problems of research design encountered in the study of ageing, and some of the fundamental theoretical issues involved in the concept of ageing. Some of these issues are taken up in the two succeeding chapters on time and ageing by Reichenbach and Mathers, and biological periodicities by Landahl. Ageing is a process closely connected with the passage of time, and Birren and his collaborators may well be right in thinking that the systematic theoretical foundations of ageing research have their foundations in the theory of time.

L. S. HEARNshaw

THE NATIONAL AVIATION MUSEUM, OTTAWA

By S. L. ROBERTS

Department of Northern Affairs and National Resources, Ottawa

THE story of Canadian aviation, an important chapter in Canada's national development which many Canadians have embellished with their distinctive contributions, is presented in the new National Aviation Museum at Ottawa.

The National Aviation Museum, situated in the new Uplands Air Terminal, was opened recently by the Hon. J. Angus MacLean, Minister of Fisheries. Through the displays, visitors can trace the progress of Canadian aviation from the experiments of the pioneers in the early 1900's to the complex jet and rocket developments of present time.

The basic theme of the Museum is "Canada's Contribution to Aviation, and Aviation's Contribution to Canada". To carry out this theme, reliance could not be placed on the display of historical items alone. These relics of the early days of the aviation have been placed mostly in the primary display area, which is concentrated on the pioneering days of flight in Canada. The rest of the displays are of the didactic type, using photographs, models and selected samples of actual aircraft and aviation parts, instruments, accessories and equipment to portray the story of civil aviation in Canada.

There are nine distinct sections to the Museum. From the pioneer section visitors pass to the area in which the development of piston-engines, navigation instruments and electronics is presented. The next area illustrates aviation's supporting services—air traffic control, airport construction, weather, aviation medicine, communications, maintenance and overhaul, search and rescue, and the radar detection chains in northern Canada. The operations section illustrates the development of commercial airlines and the use of aircraft in photography, mapping, geological survey, forest fire fighting, insecticide spraying, and communications.

The sections dealing with jets, rockets and research demonstrate the increasing complexity of aircraft design and the extent to which aeronautical research has expanded. Two other sections follow, one showing some of the development of the aviation manufacturing industry, and the other the extent that the demand of aviation for new techniques and materials has encouraged the development of Canadian industry and made the country less dependent on imports of manufactured articles.

One rather novel feature is a 'children's museum', where much thought has been given to making the displays interesting and attractive to children. Here young visitors can learn to identify the parts of aircraft and understand their function, and play with small plastic aircraft models on a toy landing field.

One full-sized aircraft, displayed in another part of the building, forms part of the Museum. This is a flying replica of the *Silver Dart*, the machine built on Cape Breton Island by the unique aeronautical research group of Canadians and Americans led by

the inventor of the telephone, Alexander Graham Bell. The *Silver Dart* made the first flight in Canada—and the first flight by a British subject in the Commonwealth—in February 1909, with a Canadian pilot, J. A. D. McCurdy, at the controls. This historic aircraft was duplicated, with a few practical modifications, by L.A.C. Lionel McCaffrey and other airmen of the R.C.A.F. and flown by W/C Paul Hartman at Cape Breton Island in February 1959 in a re-enactment of the first flight.

Although space limitations prevent the display of other full-sized aircraft, models of Canadian aircraft types have been provided by British, Canadian and American manufacturers for display in the Museum. The 1/24 scale, as followed in the Science Museum at South Kensington, has been adopted as the standard for the aircraft models, though many of the models given or lent to the Museum are of other scales.

The Museum attempts to provide a clear and comprehensive presentation of aviation in Canada within the limitations of a small area. It is remarkably complete and contains many individual items of great interest. Among these are a 'mock-up' of the Canadian-developed *Velvet Glove* air-to-air missile,

Fig. 1. The original *Silver Dart* engine and a model of the aircraft

Fig. 2. Model of the *Dew Line* activities and aircraft used in supplying stations

controllable-pitch propellers invented by the New Brunswick pioneer Wallace R. Turnbull during 1923-27, an operating model of the early wind-tunnel used at the University of Toronto in the 1920's, and a steering wheel from the British airship *R-100*. In appearance, the Museum gains variety by using distinctive colours and surface textures to identify the display areas, and by arranging the walls in an irregular pattern.

In keeping with the technological atmosphere of the Museum, some individual displays can be set into operation by the public. Repeaters provide a recorded sound narration in French or English to explain the more technical aspects. Among these operating exhibits are demonstrations of the effect of changes in atmospheric pressure on sparking plugs, and of the contrast of photoelastic stress between large radii and sharp angles.

The National Aviation Museum of Canada has been a long time in the making. A start was made as early as 1929, when J. H. Parkin, now senior consultant to the Division of Mechanical Engineering of the National Research Council, brought a number of aircraft engines and models of wind tunnels to the National Research Council. In 1932 the Council set up a small aeronautical museum, devoted chiefly to engines, in the basement of one of its Ottawa buildings, but this museum was closed early in the Second World War.

Fortunately, the rare items from aviation history that had been collected were stored and well preserved through the years. In 1956 an Associate Committee of the National Research Council was formed, with General A. G. L. McNaughton as chairman, to study the problems of creating a National

Aviation Museum. Much stimulus was provided by the National Co-ordinating Council for the Golden Anniversary of Flight in Canada, a group representing aeronautical and flying associations and organizations which planned the 1959 anniversary programme.

The National Aviation Museum was established with funds provided by the Canadian Government and with funds or displays given by many firms in Canada, Great Britain and the United States. The National Research Council collection served as the nucleus of the Museum, and this material was assembled with the new donations into an organized museum by the staff of the Engine Laboratory, Division of Mechanical Engineering, National Research Council, under the direction of its chief, M. S. Kuhring.

Although the National Aviation Museum is designated as the first unit of a Canadian Museum of Science, it will be some years before permanent accommodation is provided. As a temporary measure the Museum is suitably located at Ottawa in the new Uplands Air Terminal. From the windows of an observation room which occupies one corner of the Museum, aircraft can be observed landing and taking-off from one of the busiest of Canada's airfields. Air travellers may also enjoy the experience of visiting this unique aviation museum while waiting for their flights.

The National Aviation Museum is administered by the Department of Northern Affairs and National Resources, the Federal department which administers the National Museum of Canada, the Canadian War Museum, and a number of small historical museums throughout the country.

BIOLOGY IN THE TROPICS

AT the Cardiff meeting of the British Association for the Advancement of Science on September 1, Dr. G. S. Carter, of the Department of Zoology, University of Cambridge, set the stage in his presidential address on "Tropical Climates and Biology" to Section D (Zoology) for a session on the importance of the tropics to zoology. In the session Dr. Carter's address was followed by a paper on evolution within the tropical belt by Prof. J. E. Webb, of University College, Ibadan, Nigeria, and by another on tropical fish communities by Dr. Rosemary McConnell (*née* Lowe), lately of East Africa and now fisheries research officer in British Guiana.

Dr. Carter began by relating that when he was young he was told by his elders that a zoologist's education was not complete until he had visited the tropics and worked on a tropical fauna with its richness and variety of animal life. He believed that this is still true to-day although not, perhaps, for quite the same reasons that led our predecessors to think so. The richness and variety still remain largely unexplored, but we have come to realize that results of work in the tropics are frequently of great general interest to the biologist and may not be such as might be expected from knowledge of the biology of temperate climates.

Both Dr. Carter and Prof. Webb stressed the importance of climate in determining the fauna and flora of a region, and showed that the most unchanging of all land climates is to be found in the forests of the humid tropics. Temperate climates, although more moderate in regard to average temperature, in fact have greater seasonal and diurnal variation in this respect than the humid tropics, and thus present a more stringent environment for animal and plant life. In the tropics rainfall is more important than temperature in determining differences between environments, for the regions of high rainfall are covered by forest that gives way to grassland or savanna of increasing dryness in areas of low precipitation and this in turn to desert. Prof. Webb showed that the boundaries of the vegetational zones in Nigeria are related not so much to the amount of the rainfall but to the relative length of the dry period in each year. More accurately it may be said, as Dr. Carter pointed out, that the nature of the environment is controlled by the proportion (l/g) of the gain of water to the environment to its loss, not only in evaporation and run-off but also in transpiration from the vegetation and percolation into the soil. In the rain forests the value of l/g is of the order of 0.2, so that much of the water flows off the land and the environment is humid. In deserts, l/g may be as high as 200 and in savanna it is probably often near unity. This ratio l/g also controls the diurnal and annual ranges of temperature which are low in humid environments and high in the desert.

Dr. Carter mentioned several examples of work on tropical biology that has given results not to be expected from our knowledge of the temperate regions. In tropical swamps—an environment from which vertebrates and probably many other terrestrial animals almost certainly emerged from water on to land—the water is for all practical purposes stagnant. The content of nutrient salts in these

swamps is often high, and at first sight it would be expected that the phytoplankton would be plentiful, but, in fact, both animal and plant plankton are sparse. It seems that the failure of the phytoplankton to grow is due partly to the shallow penetration of light into the shaded and highly coloured water, and partly to the low concentration of dissolved oxygen in the water at levels less than 5 per cent saturation. Dr. Carter suggested that the low concentration of oxygen might be a result of the absence of photosynthesis together with a lack of overturn of the layers of the water. Under conditions giving rise to a steep temperature-gradient from the surface downward with the surface 8–10 degrees C. higher than water at 12–18 in. depth, the water becomes permanently stratified, the lower layers receive no oxygen and in parallel come to contain a high concentration of free carbon dioxide, up to 70 c.c. per litre, which cannot escape by diffusion. This is, therefore, a very difficult environment for animals, and all the fauna shows adaptation to life in a deoxygenated habitat and has developed accessory breathing organs and the like. A study of this question of permanent stratification in shallow tropical waters is clearly important for their future economic development.

Equally unexpected results have been given by work on the sulphur content of tropical fresh waters in Africa by Beauchamp (*Nature*, 171, 769; 1953), where its lack appears to be a limiting factor in the growth of the aquatic fauna. It seems that the sulphur is absorbed from the water of the lake by the planktonic fauna and flora and carried down to the mud in their dead bodies so that the water becomes denuded of sulphur. In the mud the organic sulphur compounds are preserved without breakdown even for the several thousand years required for the deposition of 10–15 m. of mud. Plants rooted in the mud are able to absorb sulphur from this store, which is apparently the only means whereby the sulphur can be carried back into the water. Lake mud can thus be used to improve the fertility of tropical soils and fish ponds.

The control of seasonal rhythms of reproduction and migration in tropical animals is not easy to understand when the changes in climate are slight, yet periodicity of these kinds has been demonstrated in a wide range of equatorial animals. It may be that these rhythms are at least in part endogenous, but it seems there must be some environmental stimulus, physical or other, that controls their periodicity even though we cannot always define it. Clearly this is a subject on which further work is needed.

Dr. Carter ended with the problem of how small mammals are able to satisfy their needs for water under desert conditions without drinking and at temperatures as high as 54° C. This has been studied by B. and K. Schmidt-Neilsen ("Biology of Deserts", Inst. of Biology, London, 1954). It is quite impracticable for the body temperature of a small mammal in the desert to be controlled by sweating, and accordingly sweat glands are reduced. In this case the water balance of the animal is achieved by a reduction of all forms of water loss from the body, utilization of metabolic water, the eating of plants absorbing dew deposited during the cold desert nights and

sheltering in a burrow during the day. It is evident that this is one complex physiological problem of which there are many in regard to tropical animals.

Prof. Webb remarked that for more than a century the distribution of animals had been viewed mainly from the point of view of the zoogeographical regions, none of which is exclusively tropical, and that the fauna and flora of the tropical belt as compared with the temperate and arctic regions had escaped detailed geographical analysis. The tropical belt, however, has a physical basis and unlike the zoogeographical regions must have existed for longer than life itself. An estimate based on the distribution of species in a representative sample of groups of land and freshwater animals suggests that at least 70 per cent of the world's land species occur in the tropics and there is evidence that this is also true for land plants and marine organisms. Moreover, for tropical land animals and plants, an analysis of distribution suggests that not less than 50 per cent of these are found in the forest, most of the remainder being savanna forms. Relating these figures to the areas of the Earth's surface involved we find a density of species in the tropical forest at least three times as great as in savanna and six times that of the temperate region. Thus the number of species is high in the tropical forest and falls more or less progressively with increasing biological stringency of the environment through the tropical grasslands to the desert, on one hand, and from the tropics as a whole through the temperate to the polar regions on the other. This applies to species but not necessarily to higher taxonomic categories, such as the genus and the family where the numbers represented in the tropics may be less than elsewhere. Nor does it appear that the high number of tropical species is related to a greater biomass in the tropics, for there is evidence that this is not greatly in excess, if at all, of the biomass of the temperate region. The density of tropical species, therefore, is evidently due to greater speciation in the tropics than elsewhere, and the problem remains why this should be so.

When the distributions of the present-day families of the vertebrate classes between the tropic and temperate regions are compared, it is found that the most-recently evolved group, the birds, has a higher proportion of tropical families than the older group, the mammals, and that the proportion of tropical to temperate families falls steadily through the series reptiles, amphibians, fishes and lampreys. Moreover, the ratios of recent tropical to temperate families for these groups when plotted against the respective times of origin of the groups, as given by the age of the earliest known fossils of each, fall into two approximately parallel linear series. The first and earlier of these is the Anamnia and the second the Amniota, the break between them evidently representing the point when the reptiles achieved emancipation from water, which opened to them and their successors a new terrestrial path out of the tropics into temperate lands.

The evidence that the proportion of temperate to tropical vertebrate families has increased regularly with the age of the group suggests that each of the vertebrate classes originated in the tropics and that the rate of evolution of families has been virtually constant, first for the Anamnia and then for the Amniota, since the Ordovician for a period of 350 million years. Prof. Webb pointed out that if there is any truth in the speculation that evolution has

been proceeding at a more or less constant rate for so long, then it becomes necessary to seek some physical change in the Earth which, by regularly affecting the tropical belt for this period of time, might have controlled the rate of vertebrate evolution.

The zone of transition from tropical forest to savanna consists of an interdigitation of areas of forest and grassland with inliers of savanna in the forest and outliers of forest in the savanna. Slow fluctuation in the extent of the forest in response to climatic changes over the centuries or millenia would result in the formation of new isolated areas of forest or savanna and their subsequent re-incorporation into the parent vegetational belt. The temporary isolation of these patches of vegetation could provide conditions favourable for speciation and perhaps account in part for the high density of species in the tropical forest. If in addition there was also a very much slower, constant and prolonged shift of the land masses through the tropical belt then, at its edge, outliers of tropical vegetation would move into the temperate zone, shrinking and finally disappearing. The isolation, together with the slow environmental change, that this would cause could be part of a mechanism leading to the evolution, at a more or less constant rate, of forms adapted to temperate conditions in proportion to their numerical representation in the forest.

Prof. Webb directed attention to the work of Prof. S. K. Runcorn in "Advances in Physics" in 1955, which postulated on palaeomagnetic evidence a relative shift of the north magnetic pole from a point near the present equator west of America in the Pre-Cambrian through a wide arc crossing Japan and Siberia to its position at the present. As it is probable that the geographic pole has never been far from the magnetic north, this shift would also imply a corresponding shift of the equator. It is clear, therefore, that there may be some physical evidence for a constant and prolonged movement of the land masses through the tropical belt on which depends the suggested mechanism for the evolution at a more or less regular rate of temperate vertebrates from originally tropical forms.

Prof. Webb showed maps on which the equators of the different geological periods were drawn based on Runcorn's positions of the north magnetic pole and noted that the locations of the earliest known fossils of the vertebrate classes all lie within the tropical belts of their periods. He also pointed out that, on this evidence, the equator of the Triassic in which the Rhynchocephalia arose passed through the Bay of Plenty in New Zealand, where lives the tuatara lizard, the last survivor of that group. Moreover, the relative change in position of the equator, also on this evidence, has been about an axis between a point in the Pacific off the west coast of North America and the northern tip of Madagascar since the Silurian. These areas, therefore, may have lain continuously within the tropics for the past 330 million years and may have been the only regions on the Earth's surface to have done so. It may be significant that the Pacific location is near where the primitive mollusc *Neopilina* was recently found, while the seas off North Madagascar are the home of the living coelacanths. Perhaps these areas are the nearest we shall find in fact to the fiction of Conan Doyle's "Lost World". (Recent work by Prof. P. M. S. Blackett, Dr. J. A. Clogg and Mr. P. H. S. Stubbs in *Proc. Roy. Soc., A*, 256, 291; 1960, gives

palaeomagnetic evidence for continental drift. A reassessment of the positions of the fossil equators relative to the land masses will need to be made in the light of this new evidence for drift.)

Dr. Rosemary McConnell ended the symposium with a comparison of the fish faunas of tropical Africa and tropical America. She commented on the great complexity of the tropical fish fauna which, combined with a lack of well-defined seasons, led to many of the difficulties experienced by ecologists in the tropics. The majority of the freshwater fish species of South America and Africa belong to relatively few family groups each of which has undergone remarkable adaptive radiation. The chief of these are the catfishes, the characids and the cichlids, which are common to the two continents and comprise about 70 per cent of the fish fauna. The main difference between the faunas of the two continents is the presence in Africa of numerous species of Cyprinidae and Mormyridae, families absent from South America, where their ecological positions are occupied by the Characidae and Gymnotidae.

The Amazon is by far the richest river system in the world with well over 1,000 known species of fish, and no doubt very many more await discovery. The fish communities there are very complex, many species, often closely related, living in one area as is shown by the fact that a large seine may net as many as 100 species of fish in a single haul in certain parts of the Amazon. A similar though less-extreme situation exists in Africa where, for example, Lakes Tanganyika and Nyasa both have about 200 species of fish, most of them endemic. The question, therefore, arises as to the reason for the complexity of these tropical fish communities. Dr. McConnell suggested that a factor contributing to this could have been profound weather changes of the Quarternary. Just as in the temperate zones the ice ages probably reduced the number of fish species there, so in the tropics the corresponding pluvial and interpluvial periods may well have promoted speciation. For example, in Africa, during a pluvial period, a rise in the level of the lakes would have made new niches for the fish which would afterwards become isolated during the interpluvial period when the lake-level fell, thus providing conditions favourable for speciation. This situation of fluctuating levels in the freshwater habitats is very similar to that proposed by Prof. Webb for the forest.

Dr. McConnell remarked on the extensive adaptive radiation achieved by the Cichlidae, Cyprinidae and

Mormyridae in Africa and the Characidae and catfishes in South America, and outlined the astonishing diversity of form and habit found particularly among the catfishes. In such a complex of species the problems of how populations remain distinct and individuals of one species recognize one another for breeding purposes are not fully understood and certainly cannot be answered completely at the moment. The segregation of many of the species, particularly in the Cichlidae, has undoubtedly been maintained by differences in territorial behaviour, restrictions imposed by different food and breeding requirements and so forth. Recognition of each other by individuals within a species may be achieved again by their seeking similar environmental conditions for breeding purposes. In some cases the fish resort to sound signals for recognition and in this respect parallel many of the insects of the tropical forest. The characid of Guiana streams, *Prochilodus*, on a spawning run up river sounds like an outboard engine.

Eating and avoiding being eaten form the predominant theme in the tropics, the biotic relationships appearing to assume greater importance in the general ecology when physical conditions are stable, and much remains to be learnt about the balance between predator and prey. In the absence of well-defined breeding seasons, fish spawn at any time of the year so that young fish and fish at all stages of growth may also be found at all times of the year. The community is thus very uniform and some predators have been able to specialize in feeding only on young fish. In spite of this, however, a balance is maintained, for the food webs are too complex to allow certain species to multiply enormously and thus there is here, just as there is in the tropical forest, no species which can truly be considered dominant.

Dr. Carter remarked in closing his presidential address that, as tropical biology is at a much less advanced stage than that of temperate countries, it is less difficult in the tropics to find promising lines of work. Yet, when posts in tropical laboratories are advertised, it is not by any means always easy to find people to fill them. One reason for this may well be that the many advantages of work in the tropics are not sufficiently realized by the younger generation of biologists or, for that matter, by the older generation that advises them. Perhaps this session will have shown that the tropics offer new fields to conquer and the chance to view old problems in a new light.

J. E. WEBB

SPECIFICITY AND INHERITANCE OF ANTIBODY RESPONSE : A POSSIBLE STEERING MECHANISM

By DR. B. CINADER

Department of Medical Biophysics, University of Toronto, and Division of Biology,
Ontario Cancer Institute, Toronto

ANIMALS may be tolerant¹ to their own circulating antigens and hence to a very large number of antigenic determinants. An antigenic determinant of a heterologous protein could only induce an antibody response if it were different from any of the determinants of the autologous proteins. The specificity of the antibody response would thus depend on

the relation between the structure of autologous and heterologous antigen. Furthermore, the determinant sites of autologous proteins are not always the same in individuals of the same species, and as a consequence the determinants of a heterologous protein which could elicit an antibody response would not be necessarily identical, in composition or number, in

two individuals of the same species. Since the structure and sequence of amino-acids of autologous proteins is genetically controlled, the antibody response which would depend on these would also be inherited and would be different for different antigens. The validity of this hypothesis depends on the following premises.

Immunological tolerance to defined antigens is as general a phenomenon as the antibody response itself. It depends on the individual chemical determinants of the antigen and not exclusively on the antigen as a whole. If two antigens share one or several determinants, tolerance to one antigen can affect the immune response to another. Since immunological tolerance to heterologous antigens is a general phenomenon, it may be assumed that it can also be induced by autologous proteins and that conclusions valid for tolerance to heterologous proteins apply equally to isologous proteins. Finally, autologous proteins of different individuals differ in amino-acid sequence (and tertiary structure) and these differences are under direct genetic control.

Before discussing the implications of these statements, their validity will be examined.

The injection of a heterologous protein into a newborn animal prevents antibody formation to this particular antigen during part or all of the adult life of the animal¹⁻¹³. Acquired immunological tolerance to defined antigens has been induced in rabbits, calves, goats, mice and birds. The antigens used have been various serum albumins, globulins, ribonuclease, azo serum albumin, and yeast antigens. The variety of different species and of different antigens involved suggests that tolerance is as universal as the antibody response itself. Some experimental observations may appear to detract from this generalization. There are reports which indicate that tolerance in chickens^{9,15}, and possibly in rabbits¹⁰ and in mice¹¹, may be of short duration and may require for its maintenance reinforcement by antigen during adult life. There is no need to consider the general significance of these reports (see ref. 16) here since, in the situation to be considered, antigen would be available during adult life. There are also several reports of failures to induce immunological tolerance, particularly when red cells are injected at birth, and these need to be considered in some detail since they affect the acceptance of tolerance as a general phenomenon.

Some failures to induce tolerance can, no doubt, be accounted for by the induction of tolerance being dependent on the quantity of antigen injected^{17,18}. In order for tolerance to be demonstrated, every antibody-forming cell or its mother cell would have to be affected. If only a relatively small proportion of these cells has a tolerance-inducing encounter with antigen, the slight decrease in antibody production may be obscured by the wide scatter of the amount of antibody produced by normal rabbits. If, on the other hand, the dose injected at birth is such as to leave a very small proportion of antibody-forming cells unaffected, prolonged immunization would be required before the unaffected cells have multiplied sufficiently to produce a detectable amount of antibody. During the early stages of immunization it would, consequently, appear as if no antibody were being synthesized; after some time and after repeated challenge, formation of antibody would reach a level at which it can be detected.

Apart from failure to induce tolerance, experimental failure to prove its successful induction must be considered in this connexion.

The presence of antigenic impurities in the preparation used for injection at birth can lead to results which may be misinterpreted as failure to induce tolerance to the principal antigen. Tolerance to the principal antigen may have been induced, while an impurity may have been present in quantities too low to induce tolerance but sufficient to give rise to antibody during subsequent immunizations¹⁴. This source of error can occur with any purified protein and can only be excluded by a rigid demonstration that antibody found in an animal injected at birth is directed against the principal antigen injected.

This difficulty¹⁴ occurs also, and in a very complex situation, when heterologous cells, not capable of propagation, are injected at birth. The cells consist of a large number of different antigens, all acting independently in inducing tolerance, all present in different relative quantities. The antigens which are present in very low concentration on the surface of such cells might not induce tolerance. More abundant antigens would induce tolerance. Subsequent immunization would lead to formation of antibody to the 'rare' antigens only. It might be concluded that tolerance had not been induced, which is correct on the cellular—though not on the antigen—level.

In the light of the foregoing experiments and considerations, it may be suggested that rigid criteria must be observed to demonstrate that animals injected at birth have failed to make antibody to the principal antigen injected. For this reason, negative reports—that is, reports of failure to induce tolerance—must be treated with caution, while the reports that tolerance can be induced to defined proteins can be taken at their face value and can be accepted as an indication that immunological tolerance is a general phenomenon.

The second question raised, as to the specificity of acquired immunological tolerance, has been approached by means of model experiments. The following experimental conditions may be considered^{6,7}.

Antigen injected at birth	Antigen injected during adult life
Human albumin	Azo-human albumin
Azo-bovine ribonuclease	Azo-human albumin

The system for examining antibodies has been based on agglutination inhibition^{6,7,14}.

Immunization with azo-human albumin of animals tolerant to human albumin does not elicit a demonstrable antibody response to azo-human albumin in most of the animals. However, 20–30 per cent of the animals tolerant to human albumin make antibody to azo-human albumin. This antibody cannot be inhibited by the prior addition of human albumin to serum, but can be completely inhibited by the prior addition of azo-human albumin. Such antibodies are thus essentially directed against the modified part of the molecule and are not directed against the protein moiety of the unchanged molecule. Animals injected with azo-ribonuclease at birth and afterwards immunized with azo-human albumin also show two different responses. All control animals and the majority of the animals injected at birth make antibody both against the protein moiety and against the modified part of the molecule, but a small number of animals make antibody directed against the protein

moiety and not against the modified part of the protein.

There is thus some evidence for tolerance being dependent on antigenic determinants. Consequently the immune response of an adult tolerant animal is not only inhibited with respect to the antigen injected at birth but is also reduced when an antigen is injected during adult life which shares determinants with the antigen injected at birth. This accounts for the observation³ that rabbits tolerant to bovine albumin produce significantly less antibody to egg albumin (known to cross-react with bovine albumin¹¹) than do animals not tolerant to bovine albumin.

The general conclusion that tolerance depends on antigenic determinants, though possibly in some way also on the molecule as a whole, seems justified.

If immunological tolerance¹ can be induced by heterologous proteins in general, it can presumably also be induced by autologous proteins; this would not only serve as a safeguard against antibody formation to circulating autologous proteins but would also have an effect on the specificity of the antibody response to heterologous antigens. Tolerance to one heterologous antigen can affect the antibody-response to another one if an immunological determinant is shared by both antigens. Assuming a similar effect as the outcome of tolerance to an autologous protein, an adult animal would not only be prevented from making antibody to the autologous protein as such but also to any determinant of the autologous protein. A heterologous protein could contain one portion consisting of an amino-acid sequence or determinant surface configuration which also occurs in an autologous macromolecule; this particular determinant would then be excluded, as an inducer of antibody, in a response to the heterologous antigen. Since a large number of different proteins circulates through the body, it would seem likely that a considerable number of determinants would be excluded from antibody induction, so that the specificity of the antibody response to proteins might be guided, to a considerable extent, by the tolerance developed to autologous proteins. Furthermore, the quantity of the antibody synthesized in response to a heterologous antigen might similarly depend on tolerance induced to autologous proteins, since the number of antibody-inducing determinants on a heterologous antigen would depend on the number of determinant sites not shared with autologous proteins of the responding animal.

The possible influence of tolerance to autologous proteins on the genetic control of the antibody response is perhaps the most interesting of the probable consequences of tolerance to isologous proteins; genes would act through an intermediary process.

In the model system already mentioned^{6,7}, azo albumin, which is normally a 'good' antigen, had become a 'bad' antigen in animals which were tolerant to human albumin. Naturally induced tolerance to an autologous protein could presumably act in the same way as experimentally induced tolerance to heterologous protein has been demonstrated to act. It is thus sufficient to assume that the inheritance of the extent of antibody-response is mediated through the structure of autologous proteins as a consequence of acquired immunological tolerance to autologous proteins, and it is not necessary to assume that the response to all antigens should be under direct and independent genetic control.

The amount of antibody synthesized would depend, among other factors, on the number of sites on an antigen which can give rise to antibody, that is, to the number of determinants which are not excluded by tolerance to autologous proteins. The determinant sites which would be excluded as antigenic determinants would be under genetic control in so far as the amino-acid sequences and structure of autologous proteins are under genetic control. Consequently, differences between the response of different individuals would be attributable to differences in the structure of their proteins. It is known that serum globulins in rabbits¹⁰, guinea pigs¹¹, cattle¹² and man¹³; haemoglobin in man¹⁴, in cattle¹⁵ and in sheep¹⁶; haptoglobin in man¹⁷; and albumin in man¹⁸ are under individual genetic control and differ in different individuals. It is likely that this will be found to apply to other, if not all, proteins. Even if these differences should affect a very small portion of the amino-acids, it may still exercise a profound effect on tertiary folding. Thus antibody response to different amino-acid sequences¹⁹ would be excluded in different individuals. As a consequence of this genetic variation between determinants, the determinants excluded as immunogens would vary from one individual to the other and a heterologous antigen might have many more determinants able to elicit antibody formation in one individual than in another. This would result in differences in the quantity of antibody produced by different individuals to the same heterologous antigen and would be inherited.

If the foregoing considerations are applicable, and if auto-immune disease can ever occur as a consequence of the breakdown of tolerance, it should be accompanied by a change, however small, in the specificity and nature of the entire antibody-response. This might permit an experimental discrimination between auto-immune disease caused by the release of a normally 'secluded' antigen to which tolerance had never been established, and auto-immune disease caused by breakdown of previously established tolerance.

There is suggestive, if not conclusive, evidence that differences in the antibody-response may be inherited. From an immunochemical point of view, a conclusive analysis has to be carried out with homogeneous, molecularly defined antigens.

An antigenic mixture can be used if one particular molecular species can be identified by its biochemical action, so that the antibody-response can be measured in terms of the inhibition of the biological or biochemical activity of the antigen.

Gorer and Schütze²⁰ have shown that the quantity of antibody produced in response to immunization with the *H* and *O* antigens of *S. typhi-murium* and *S. enteritidis* is different for animals of different strains and that the relative quantity of antibody made by each of these strains to each of these antigens is not the same. Similar observations have been reported by Ipsen²¹ with respect to the response of inbred strains of mice to tetanus toxoid, the average response being different for each strain of mice and the relative quantity of antibody produced after primary and after secondary immunization being the same. Scheibel²² has been able to produce, by inbreeding, two strains of guinea pigs differing in their capacity for the production of diphtheria antitoxin.

Sobey²³ measured the heritability of the rabbit's response to tobacco mosaic virus by assaying the

quantity of antibody produced by parents and their offspring to a secondary response to tobacco mosaic virus, and by measuring the regression of mid-parent offspring in a cross-bred population of rabbits. This regression gave a heritability $h^2 = 0.876$, S.E. 0.09.

The experiments of Gorer and Schütze³⁰ have indicated that the antibody-response for different antigens may be inherited independently (see also ref. 34). This is also indicated by a recent observation with purified antigens. Bovine ribonuclease, a fairly 'good' antigen in wild-type rabbits, was found to induce practically no antibody in white Himalayan rabbits⁶. However, other antigens, for example, human albumin or azo-human albumin, elicited as high an antibody titre in white Himalayan rabbits as in wild-type rabbits. It would therefore seem that the genetic evidence is compatible with the prediction that the extent of the antibody-response to a given antigen is inherited, and also that the capacity for antibody-response to different antigens may be inherited independently.

On the basis of the considerations outlined, it is proposed that the antibody-response is inherited independently for different antigens, that the inheritance is not under direct genetic control, but that it is controlled indirectly by tolerance to autologous proteins; inherited differences in the antibody response of different individuals being attributable to the genetic differences between their constituent proteins.

OBITUARIES

Dr. H. E. Wimperis, C.B., C.B.E.

On July 16 Harry Egerton Wimperis, first director of scientific research at the Air Ministry, past president of the Royal Aeronautical Society and a Crown governor of the Imperial College of Science and Technology, London, died at the age of eighty-three.

His was a full life, with perhaps more than a usual mingling of happiness and vicissitude and of reward and injustice. The death of his father while Dr. Wimperis was in his first year and the struggles of his mother to educate him, shaped his early life. At the age of fifteen he was apprenticed to an engineering firm, but his boyish love for astronomy led him to write to the Astronomer Royal, who must have been greatly attracted by the young Wimperis, for he spent several hours in showing him the Royal Observatory and advised him to seek entry into the Royal College of Science and thence to Cambridge. This advice was taken, and after happy years at the Royal College of Science, he was awarded, in 1898, a Whitworth Scholarship and a scholarship at Gonville and Caius College.

Academically, Wimperis did very well at Cambridge, for which he had a life-long affection; but his social life there was restricted by the need to

provide a home for his mother. His debt to her, which he gladly paid until her death at a great age, led him to decline a fellowship of his College; this was the end of a dream of a life devoted to astronomy. Then followed a period with Messrs. Armstrong Whitworth until he was appointed, from hundreds of applicants, engineering adviser to the Crown Colonies. In London, close friendship with many men famous in the fields of the arts and humanities, and membership of the Athenæum (in his thirties) filled gaps caused by a forced life of specialization; these men must have helped him to develop an inherent lucidity of expression, for it was once said of him, "If you want something new, get Rutherford to invent it and Wimperis to explain it". His several books on technical subjects are indeed models of clarity.

Membership of the Royal Naval Volunteer Service, a fascination for aircraft and an inventive mind formed the pattern of his work during the First World War. Of his many inventions, the best known was his course-setting bomb-sight, which was introduced in 1917, and with various modifications remained the standard bombing aid until 1939. During the First World War, a small laboratory, known as the Air Ministry Laboratory, with Wimperis as its superintendent, came into being in a few rooms

provided by the Imperial College. Although the scientific staff under Wimperis was never more than half a dozen, the laboratory was no politician's plaything but one which for several years after the War continued to be an outstandingly virile centre of research on such diverse fields as aircraft engines, navigation aids and the effects of bombing on ships' structures.

When in 1925 the Air Ministry decided to follow the example of the Admiralty and create the post of director of scientific research, it was no surprise to those who had worked with Wimperis that he was asked to fill it; this he did until 1937. Much might be written of Wimperis in those years, for he was eager to pursue new and seemingly unpromising ideas while possessing a flair for detecting the bogus. He encouraged the Cierva autogyro, and in 1934 caused the formation of the Committee for the Scientific Survey of Air Defence, under the chairmanship of Sir Henry Tizard, the work of which was a major factor in transforming the whole picture of air defence. Wimperis also caused a revitalization of the Royal Aircraft Establishment of his day, and, most important of all, sowed much in defence science administration that others, with more imposing titles and more generous recognition, were to reap in the decades to come.

How much a man accomplishes for all to see must be judged in relation to whether wind and tide are for or against him. As the first director of scientific research at the Air Ministry, Wimperis had an unenviable task. Not all Civil servants were happy that a scientist should hold a responsible post; the fears of senior Royal Air Force officers led to the ridiculous edict that Wimperis was to have nothing to do with armament, that is, with the chief purposes of Service aircraft. Others caused a ban on concern with lighter-than-air craft, a restriction which did not prevent Wimperis from protesting against the premature and disastrous flight of the *R 101*. On a lighter note, it is amusing to recall that when Wimperis asked that a copy of *Nature* should be regularly provided for him, discreet inquiries revealed that it was not a salacious journal! By the exercise of patience, wisdom and courage, Wimperis gradually enhanced the respect for science in the Air Ministry and when he retired in 1937 the dictum was dying that "a scientist should be on tap but not on top".

On retirement, Wimperis accepted an invitation to Australia to advise the Commonwealth Government on aeronautical research. It was during this visit that the University of Melbourne conferred on him the honorary degree of doctor of engineering. Largely as a result of Wimperis' recommendations, a Division of Aeronautics was set up under the Australian Committee for Scientific and Industrial Research and a chair of aeronautics established at the University of Sydney, though Wimperis could not have foreseen that aeronautical research and development in Australia would be hindered by a reluctance in that country to manufacture aircraft.

During a stay in Singapore, Wimperis developed tropical sprue, which for twenty years was to call for fortitude on its victim's part and for devotion to his special needs by his wife, who survived him by only three weeks. In spite of a gradually increasing physical frailty, his range of interests widened further, and for several years he was convenor for the atomic energy study group at Chatham House.

One who knew him well, wrote these words of him: "Wimperis at the Air Ministry could be stern and

biting, never suffering fools or the lazy or the self-deluded gladly but he was tender and helpful to the eager, the struggling and to those who showed courage in difficulties. He cared intensely for truth, honesty and intellectual and personal integrity and had a deep regard for some who stood for complementary values".

Add to these attributes a strong sense of humour and we have a fair picture of Dr. Wimperis, who survived many of his friends and is mourned by many more.

A. P. ROWE

Mr. W. J. Chalk

MR. W. J. CHALK, a member of the engineering staff of the British Broadcasting Corporation, died suddenly on September 24 at the age of sixty-one. His early interest in the field of communications led to his active service during the Second World War in the Royal Signals. He retired with the rank of lieutenant-colonel after having held a number of staff appointments as Radio Planning Officer in Europe and in the Middle- and Far-East. After the War he became a member of the Allied Control Commission in Germany; and, as the liaison engineer with the North-west German Broadcasting Organization, he represented the United Kingdom High Commission at the European Broadcasting Conference at Copenhagen in 1950.

Mr. Chalk joined the British Broadcasting Corporation in 1951, and, as a member of the Engineering Information Department, he became responsible for matters concerning frequency allocations and radio interference problems in the broadcasting field. His earlier experience in world-wide communications made him a valuable member of the United Kingdom delegation at international conferences. During recent years he had participated in the plenary assemblies of the International Radio Consultative Committee held at Geneva (1953), Warsaw (1956) and Los Angeles (1959). In 1959, also, he was a member of the British Broadcasting Corporation's delegation to the Administrative Radio Conference in Geneva, which established revised regulations and frequency allocations for the conduct of international radio communications of all types. His work in this field made him widely known both in Britain and overseas. He was very popular with both his British and his foreign colleagues, and had a reputation for exercising a sound judgment on all the problems with which he was concerned. R. L. SMITH-ROSE

Prof. E. W. Goodpasture

THE death of Prof. Ernest W. Goodpasture at the age of seventy-nine is reported from the United States. He was a pioneer in the field of the pathology of virus infections.

Goodpasture was born in Tennessee, and there received his medical training at Vanderbilt University, Nashville, where he was for so long to hold the chair of pathology. He went to Yale and to Baltimore for postgraduate training; at Johns Hopkins he held a Rockefeller fellowship in pathology. In 1929 he was called to the chair of pathology at Nashville and here he remained until 1955.

His early work in the virus field was on herpes simplex, particularly on the progression of the virus along nerves. Turning to the pox group, he studied the inclusion bodies of fowl-pox, and in 1931, with

A. M. Woodruff, cultivated the virus on the chorio-allantoic membranes of fertile eggs. Rous and Murphy had twenty years earlier used a similar technique in studies of tumours, including the Rous sarcoma; but Goodpasture and his colleagues really introduced the developing egg into virus research. Later, Burnet improved the method by showing how to make an artificial air-sac. In 1938 Goodpasture showed that viruses would grow after inoculation into the amniotic cavity of chick embryos; and this method, too, was taken up and developed by Burnet, and other workers. For many years Goodpasture worked with fertile eggs and used them for many purposes and to great advantage. He grew vaccinia on chorioallantoic membranes and advocated the use of such material for vaccination against smallpox. He grew 'difficult'

viruses such as herpes zoster on grafts of human skin growing in eggs. He studied the behaviour in cells of egg membranes of some specialized parasites among the bacteria such as those of typhoid and tularaemia. The laboratory study of mumps really begins with his demonstration that monkeys can be infected by inoculation into their parotids.

Goodpasture held many important appointments, including that of scientific director of the International Health Division of the Rockefeller Foundation. On his retirement from Vanderbilt in 1955 he went to work at the Armed Forces Institute of Pathology in Washington. He was a member of the National Academy of Sciences and of the American Philosophical Society and received many honours.

C. H. ANDREWES

NEWS and VIEWS

Nobel Prize for Chemistry

PROF. WILLARD F. LIBBY has been awarded the Nobel Prize for Chemistry for 1960 in recognition of his work on the carbon-14 method of age determination. In a series of experiments carried out during the period following his appointment as professor of chemistry at the Institute of Nuclear Studies, University of Chicago, Prof. Libby demonstrated the presence of carbon-14 in Nature at a level close to that which he had predicted, and showed that its distribution throughout the world-wide carbon exchange reservoir is substantially uniform. He then pointed out that the death of an organism would prevent further exchange of its carbon atoms with those of the reservoir and that consequently a measurement of the residual carbon-14 activity of dead material could be used as a basis for an age determination. The practical application of the method necessitated the development of an experimental technique capable of measuring accurately, and on a routine basis, the extremely low levels of carbon-14 activity which are found in ancient materials. Libby's success in this direction can best be judged by the list of nearly a thousand dates produced by the Chicago dating laboratory during its period of operation. The importance of the method is incalculable, for it provides not only an absolute method of dating independent of hypothetical considerations covering the past 40,000 years or so, but also one which is of world-wide application to a variety of commonly occurring materials. Archaeology, geology, oceanography and climatology have all benefited and will continue to do so in the future from the applications of Libby's fundamental researches.

Nobel Prize for Physics

THE announcement of the award of the Nobel Prize for Physics for 1960 to Prof. Donald A. Glaser of the Radiation Laboratory, California, has given pleasure to all who admire the way in which a young man not only conceived a brilliant idea but also, using commonplace physical ideas as a basis for his experimental work in an unexplored field, and working practically alone, presented the nuclear physicist with a powerful new tool—the liquid bubble chamber. The formation of bubbles along the track of an ionizing particle occurs in a medium of much greater stopping power than the gas in a cloud chamber,

yet because of the short time (only a few milliseconds) during which the liquid is rendered sensitive to such bubble formation it is possible to follow the various products of a particular nuclear reaction without the ambiguity, inherent in nuclear emulsions, caused by the presence of many other, extraneous, tracks. Chambers containing hundreds of litres of liquid, set up beside existing high-energy particle accelerators, can now produce photographs of nuclear events every few seconds and in this way not only has the existence of the neutral cascade particle been established but also new experimental data are being made available at such a greatly increased rate that only by the use of automatic measuring devices can the fullest advantage be taken of Prof. Glaser's great contribution to physics.

Royal Society: Award of Royal Medals

H.M. THE QUEEN has been graciously pleased to approve recommendations made by the Council of the Royal Society for the award of the two Royal Medals for the current year as follows: to Sir Roy Cameron, professor of morbid anatomy at University College Hospital Medical School in the University of London, for his distinguished contributions in the field of cellular pathology; to Prof. A. C. B. Lovell, professor of radio astronomy in the University of Manchester and director of the Nuffield radio astronomy laboratories, Jodrell Bank, for his distinguished contributions to radio astronomy.

Applied Mechanics at Nottingham:

Prof. G. B. Warburton

DR. G. B. Warburton, who has been appointed to the recently instituted chair of applied mechanics in the University of Nottingham, studied at Peterhouse, Cambridge, and was awarded first-class honours in the Mechanical Sciences Tripos in 1944. As a demonstrator at Cambridge, he was attached to a research team investigating stresses set up in ships' plates due to welding. Later he became an assistant lecturer at University College of Swansea and, in 1947, joined the engineering staff at the University of Edinburgh. After varied teaching experience, Dr. Warburton was appointed head of the Postgraduate School of Applied Dynamics which was formed at Edinburgh in 1956, details of which appeared in *Nature*, 179, 1177 (1957). His research work at Edinburgh has

been in the field of mechanical vibration and his published work has been concerned mainly with the vibration of cylindrical shells and plates, and the propagation of ground vibration from machines to structures. The former work has been used in the determination of natural frequencies of aircraft, missiles and submarines.

Liverpool Observatory and Tidal Institute:

Dr. A. T. Doodson, C.B.E., F.R.S.

DR. A. T. DOODSON has recently retired from the directorship of the Liverpool Observatory and Tidal Institute. After graduating from the University of Liverpool in 1912, Doodson spent a short time in the electrical industry. During the First World War, he worked with Prof. Karl Pearson on problems which included the trajectories of anti-aircraft missiles. The Tidal Institute was formed in 1919 on the initiative of Prof. J. Proudman, who became the director, with Doodson as secretary. When the Institute was combined with the Liverpool Observatory in 1929, Dr. Doodson became associate director of the joint institution, and later, in 1946, its director. A paper published by Doodson in 1921, giving a complete revision of G. H. Darwin's schedule of the harmonic constituents of the tides, provided the foundation for much of his later work on tidal analysis and prediction. In collaboration with Proudman, Doodson developed methods for the construction of co-tidal charts based on observed tidal elevations and currents. They also published a series of papers on the theory of tides in oceans bounded by meridians. Another line of research, started by Doodson in 1923, on the meteorological effects on tides, has led to important advances in methods of forecasting storm surges. At the same time as he was carrying out research, Doodson greatly extended the routine prediction work, and to-day the Tidal Institute provides tidal predictions for nearly all the countries of the Commonwealth. Dr. Doodson was elected a Fellow of the Royal Society in 1933, honorary Fellow of the Royal Society of Edinburgh in 1953, and in 1955 was made C.B.E. In addition to serving on several national committees, he has taken a prominent part in the activities of the International Association of Physical Oceanography and the International Union of Geodesy and Geophysics.

British Economic Growth

A RECENT broadsheet issued by Political and Economic Planning, entitled "The Growing Economy—Britain, Western Germany and France", discusses the main factors influencing the development of industrial production and is adapted from the findings of a group which over the past three years has been working on problems of adaptation and change in British industry (26, No. 445; 17th October, 1960. Pp. 281–308. London: Political and Economic Planning, 1960. 3s. 6d.). These findings are to be published in a forthcoming report which, assuming that economic growth is a proper object of policy, considers the conditions for achieving a rate of growth comparable with that of other Western industrial nations. After comparing levels of industrial activity and growth in the principal West European countries and the United States, the broadsheet examines the role of capital in economic growth and then considers the structure and achievement of the economies of Western Germany and France, respectively. In contrast to British policy, French and German

economic policies have had marked success in stimulating economic growth, and the main conclusion of the broadsheet is that, in view of Britain's record since the War, priority must be given to the task of increasing the rate of growth. Specific suggestions include giving a high priority to measures which will encourage the release of workers from some industries and their rapid absorption by industries which need more labour. This involves stimulating industrial research into labour-saving methods, expanding educational facilities for scientists and technologists and participating in the organization of schemes to provide compensation for loss of employment, and to overcome obstacles to movement between jobs, such as housing difficulties, removal costs and re-training problems. It is urged that the trade union movement in Britain needs to be much more closely associated with the other organs of government and power in the attainment of the national economic objectives, above all, of economic growth. Publication of a more consistent series of plans governing the public sector would, it is suggested, go a long way towards providing private firms with the kind of assurance they need about the future growth of the economy, and it is probable that the economy would benefit if the Government exercised a more, rather than a less, positive influence over the investment planning of the private sector.

British Conference on Automation and Computation

THE rapid growth of automation in Britain led to a decision in 1957 (see *Nature*, 179, 948; 1957) by some twenty bodies having interests in this field to set up a central organization to provide more effective liaison between the interested bodies, to be known as the British Conference on Automation and Computation. The Conference was divided into three autonomous Groups, as follows: (1) the British Group for the Engineering Applications of Automation; (2) the British Group for Computation and Automatic Control; (3) the British Group for the Sociological and Economic Aspects of Automation Techniques. At meetings of the three Groups held on October 10, it was agreed that they should merge in a reconstituted organization. Sir Walter Puckey was elected chairman of the new Conference, with Messrs. L. T. Blakeman, J. F. Coales and H. G. Conway as vice-chairmen. Mr. S. M. Rix was elected honorary treasurer and Mr. W. K. Brasher (secretary of the Institution of Electrical Engineers, Savoy Place, London, W.C.2) as honorary secretary. The following representatives were elected to serve with the honorary officers as the Executive Committee: Dr. E. H. Bateman (Institution of Structural Engineers), W. J. Carron (Trades Union Congress), E. C. Clear Hill (British Computer Society, Ltd.), W. C. F. Heessenberg (Iron and Steel Institute), Prof. G. D. S. MacLellan (Institution of Mechanical Engineers), Prof. P. B. Morice (Institution of Civil Engineers), Sir Charles Norris (British Productivity Council), Prof. E. J. Richards (Royal Aeronautical Society), E. S. Sellers (Institution of Chemical Engineers).

The Wildfowl Trust

ALTHOUGH there were no major developments in 1958–59, the eleventh annual report of the Wildfowl Trust, by Hugh Boyd and Peter Scott, is once more a chronicle of satisfactory progress and development (Pp. 167+32 plates. (Slimbridge, Gloucestershire:

The Wildfowl Trust, 1960.) 10s. net.) The number of visitors increased during the year, finances are adequate and the scientific staff have extended their investigations by aerial surveys and other means. A valuable inclusion in this attractive report is the translation of a research article by Prof. S. M. Usjinski on the status of the Brent goose in the Soviet Union. The drawings and photographs are up to the standard expected from Slimbridge.

The National Research Council of Canada

DETAILS of the grants totalling 9.37 million dollars in 1959-60 from the National Research Council of Canada in its forty-third year in support of research at Canadian universities in science, engineering and medicine, show an increase of 2.62 million dollars on 1958-59 and of 6.25 million dollars on 1955-56; they are contained in a report issued by the Council, which includes also a Supplement to the 1958-59 report (Pp. ii + 213 + xi. Ottawa: National Research Council of Canada, 1960. 50 cents). Of this, 8,586,265 dollars were in direct support, 76.7 per cent being for scientific and engineering research and 23.3 per cent for medical research, while of the total, 84.6 per cent represented 958 research grants to members of university staffs and 15.4 per cent provided 450 postgraduate scholarships and fellowships. Of the indirect support, 39.4 per cent was for contributions, grants, etc., to scientific organizations and functions and 35.3 per cent for the publication of scientific periodicals. Besides a full list of grants and their recipients, fellowships and scholarships, the report includes an outline of the programme and particulars of the membership of the administering bodies.

Atmospheric Pollution

A RECENT publication entitled "The Investigation of Atmospheric Pollution" includes the thirty-first annual report of the Atmospheric Pollution Research Committee of the Fuel Research Board for the year ended March 31, 1958, and gives in synoptic form information regarding the research projects considered during that period (Department of Scientific and Industrial Research. Pp. iv + 164. London: H.M. Stationery Office, 1960. 8s. net). Smoke from railway locomotives, which are responsible for one-seventh of all the smoke discharged to the atmosphere, has been investigated. Other subjects considered were, instruments for measuring air pollution, air pollution by fluorine compounds, fumes from coke fires, smoke abatement in the iron and steel industry, and air pollution and health. The second part consists of the report of the Director of Fuel Research on the investigation of atmospheric pollution. Here more details are given on the emission of pollutants to the atmosphere, with some indication of the sources of smoke and sulphur dioxide from various fuels. From the data available it would appear that there is a steady decrease in the amount of smoke emission to the atmosphere since 1955-56, and during the same time there has been no increase in the sulphur dioxide concentrations in the atmosphere. The report states: "This shows without any doubt that the concentration of sulphur in the air in this country [Britain] is not increasing". There is also some interesting information on the smoke and sulphur dioxide concentrations in the City of London. Some particulars are also given about the work of the Fuel Research Station on the production of reactive domestic coke, smoke elimination from boilers, combustion of oil fuel, exhaust gases from motor vehicles, and other

topics. The third part summarizes the results of the observations taken throughout Britain by the co-operating bodies which take part with the Department of Scientific and Industrial Research in monitoring atmospheric pollution.

Water Pollution Research

ANTICIPATING a rapid rise in the demand for industrial water, an increase in the re-use of water, and the consequent need to improve effluents, the current report of the Water Pollution Research Board, Department of Scientific and Industrial Research, announces the imminent expansion of its Stevenage laboratory by nearly 50 per cent (Water Pollution Research, 1959. Pp. vi + 115 + 4 plates. London: H.M. Stationery Office, 1960. 7s.). The report contains much detailed and valuable, but necessarily esoteric, information about the progress made with diverse investigations into the design of waste treatment plants and the pollution of rivers.

Two particularly interesting advances may be selected for further mention. Previously, laboratory trials of a new synthetic detergent had shown that it was more easily decomposed during sewage treatment than the usual detergents. To test these observations, the whole town of Luton was supplied with apparently normal packages of detergent which contained the new active agent instead of those usually employed. Less synthetic detergent reached the sewage works, and the increase in the proportion destroyed during treatment agreed with the laboratory experiments. If it proves possible to extend the distribution of this new detergent to the whole country, the condition of many rivers and water supplies should be improved. Tests on the effects of suspended mineral pollution, often a subject for speculation, have shown that concentrations which are fatal to fish, during continuous exposures of about ten weeks, are higher than those commonly found in polluted rivers. Pathological changes of the gill tissues are apparent in the dead fish.

Biological Engineering Society

THE first meeting of the Biological Engineering Society was held on October 15 at the National Institute for Medical Research, Mill Hill. About 100 participants assembled in the morning to listen to a series of short papers, each describing a demonstration to be held during the afternoon. Sir Charles Harington, director of the Institute, opened the proceedings, and in his address drew a parallel between the state of biological engineering to-day and biochemistry half a century ago. Perhaps in the years to come a fusion of the two disciplines of biology and engineering might result in biological engineering becoming as acceptable as biochemistry to-day. In the meantime, advances in biological and medical science, he said, are very dependent on advances in engineering and instrumentation, and the Society is making a valuable contribution by enabling biologists and engineers to work more closely together and to understand each other's points of view. Prof. R. F. Woolmer, the president of the Society, replied to Sir Charles, and pointed out that it was appropriate that this first scientific meeting should be held at the Institute, which in its work and organization is a good example of the way in which engineers could work together with biologists. A number of demonstrations illustrating many aspects of the work of the institute, and that of members of the Society from other centres, was given. The honorary secretary of the

Society is Dr. A. Nightingale, Physics Laboratory, St. Thomas's Hospital, London, S.E.1.

Milk Hygiene

THE second report of the Expert Committee on Milk Hygiene, set up jointly by the Food and Agriculture Organization and the World Health Organization, amplifies and supplements an earlier one published in 1957 (W.H.O. Technical Report Series, No. 197. Pp. 55. (Geneva: World Health Organization.) 2 Swiss francs; 0.60 dollars. Also obtainable from H.M. Stationery Office. 3s. 6d. net. 1960). It deals first with some of the diseases that can be transmitted through milk, and refers especially to staphylococcal and streptococcal infections, and to tick-borne encephalitis. The nature of pasteurization and other forms of heat treatment, and their importance in reducing the danger of infection from milk itself and from milk products such as butter, cheese, fermented milk, dried milk and ice cream, are discussed. The fact is stressed that if in many countries of the world milk quality is to be significantly improved, information and exhortation about hygiene will not be enough; they will have to be accompanied by some system of payment for quality. A later section of the report describes some of the problems associated with dairying in warm countries, where the standard of nutrition is frequently very low and where dairy products are very badly needed to improve the diets of the vast populations that live there. Reference is made to the production of milk in these areas not only from cows but also from buffaloes, goats and sheep. The report contains two annexes. One is a code of principles for milk and milk products prepared under the auspices of the Food and Agriculture Organization. The other contains a description of some twenty of the less-well-known milk products such as 'yogurt' and 'ghee' which are much used in parts of Europe and Asia. The report should be of particular value in those areas of the world where more dairy products are urgently required, but where, for various reasons, the production of milk and its products is still somewhat primitive and relatively little is known of the science of dairy technology.

The Night Sky in December

FULL moon occurs on Dec. 3d. 04h. 25m. U.T., and new moon on Dec. 18d. 10h. 47m. The following conjunctions with the Moon take place: Dec. 3d. 01h., Aldebaran $0^{\circ}5'$ S.; Dec. 6d. 06h., Mars 7° N.; Dec. 21d. 15h., Venus 4° S.; Dec. 30d. 07h., Aldebaran $0^{\circ}4'$ S. In addition to these conjunctions with the Moon, Mercury is in conjunction with Antares on Dec. 13d. 08m., Mercury being 5° N. Mercury is a morning star, but conditions are not favourable for observation. Venus is an evening star, and conditions for observation are becoming favourable. Venus sets at 18h. 30m., 19h. 10m. and 19h. 55m. on December 1, 15 and 31, respectively, almost four hours after the Sun on the latter date. During the month its distance from the Earth decreases from 102 to 83 million miles, the visible portion of the apparent disk from 0.744 to 0.639, and its stellar magnitude from -3.6 to -3.8 . Venus is visible in the south-west after sunset. Mars rises at 18h. 05m. and 16h. 50m. on December 1 and 15, respectively, and is above the horizon at sunset on December 31. It is retrograding in Gemini, and is at opposition on December 31. Mars is closest to the Earth on December 25, when its distance is 56 million miles and its stellar magnitude -1.3 . Mars is a very prominent object and

can be seen all night. Jupiter and Saturn set shortly after the Sun, and are unfavourably situated for observation. Occultations brighter than magnitude 6 are as follows, observations being made at Greenwich: Dec. 3d. 0h. 57.2m., α Tau. (D); Dec. 3d. 2h. 16.3m., α Tau. (R); Dec. 7d. 3h. 53.8m., 5 Cnc. (R); Dec. 10d. 3h. 25.7m., 44 Leo. (R); Dec. 29d. 23h. 43.4m., γ Tau. (D). D and R refer to disappearance and reappearance, respectively. The Geminid meteors are active during December 9-14, but conditions for observation are unfavourable. The Ursids are active during December 20-22, and conditions are favourable; the radiant is near R.A. 14h. 28m., Dec. $+76^{\circ}$. The winter solstice occurs on Dec. 21d. 20h.

Announcements

At the recent Inter-American Course of Physiopathology of Reproduction and Artificial Insemination it was decided to form a Latin-American Association for Animal Fertility. The following were elected officers of the Association: *Permanent Honorary President*, Prof. T. Bonadonna (Milan); *President*, Prof. A. Hernandez Prado (Venezuela). It is expected that sections in the different South American Republics will be established.

DR. M. R. POLLOCK, of the National Institute for Medical Research, London, will give the second Rappine Memorial Lecture on "La Sécrétion d'enzymes par les Bactéries" at 5.30 p.m. on December 2 at the Laboratoire d'Evolution des Etres Organisés, 105 Boulevard Raspail, Paris.

A MEETING on "Theoretical Rheology" is being organized by the British Society of Rheology at Reading during April 20-21, 1961. Further information can be obtained from Dr. M. F. Culpin, 8 The Broadway, Pontypool, Mon.

THE National Institute of Agricultural Botany is holding a Crop Conference at its headquarters in Cambridge during December 13-14. Further information can be obtained from the Assistant Director, National Institute of Agricultural Botany, Huntingdon Road, Cambridge.

THE eighth annual Western Spectroscopy Conference will be held at Asilomar, Pacific Grove, California, during January 26-27, 1961. Further information can be obtained from the chairman of the Western Spectroscopy Association, Roland C. Hawes, Applied Physics Corporation, 2724 South Peck Road, Monrovia, California.

THE fifth conference on "Carbon" is to be held at Pennsylvania State University during June 19-23, 1961. The conference is being sponsored by the American Carbon Committee and the Pennsylvania State University. Further information can be obtained from the chairman of the Executive Committee, S. Mrozowski, American Carbon Committee, Carbon Research Laboratory, University of Buffalo, Buffalo 14, New York.

A SYMPOSIUM on "Large Capacity Memory Techniques for Computing Systems" will be held during May 23-25, 1961, at the Department of Interior Auditorium on O Street, between 18th and 19th Streets, N.W., Washington, D.C. The symposium is sponsored by the Information Systems Branch, Office of Naval Research. Further information can be obtained from Miss Josephine Leno, Code 430A, Office of Naval Research, Washington 25, D.C.

THE PAINT RESEARCH STATION

NEW EXTENSION

THE Paint Research Station at Teddington has grown steadily in size and stature since its inception in 1926. A new extension to its already considerable premises was ceremonially opened and named the Jordan Laboratory on September 20 by Mr. E. B. Calvert, chairman of the recently formed Paint Manufacturers' Joint Executive Council. The new Laboratory is named, of course, after the founder-director, Dr. L. A. Jordan, whose outstanding service from 1926 until 1959 is commemorated on a plaque unveiled by Mr. Calvert. A further proof of the esteem in which Dr. Jordan is held was signalled by the presentation to him of the medal of the Research Association of British Paint, Colour and Varnish Manufacturers, of which the Paint Research Station is the instrument.

The opening ceremony, which was held in the new library in the Jordan Laboratory, was attended by about two hundred members and guests. At a luncheon preceding the opening ceremony, Sir Harry Melville, secretary of the Department of Scientific and Industrial Research, was the guest of honour and spoke of the continuing importance of the research association movement. Other distinguished guests at the luncheon included Mr. L. Farmiloe, president of the National Paint Federation; Mr. B. J. Nicholson, vice-president of the Society of British Paint Manufacturers; Dr. D. W. Hill, chairman of the Committee of Directors of Research Associations; Mr. P. J. Gay, president of the Oil and Colour Chemists' Association, and representatives of the Organic Coatings Division of the International Union of Pure and Applied Chemistry.

The Jordan Laboratory adds rather more than 10,000 sq. ft. of floor area to the 25,000 sq. ft. of the existing premises. The main feature of the new extension, which is a striking building of modern design, is a library of some 1,250 sq. ft. on the ground floor, with additional book storage in a semi-basement. The library—an attractive room furnished in African mahogany—and the adjacent staff common room may be combined for special occasions (the opening day, for example) to form one large assembly hall of nearly 2,000 sq. ft.

The first and second floors accommodate three large general-purpose laboratories, a section specially designed for microbiological studies, and eight smaller rooms (instrument rooms, balance rooms, dark room, stores, etc.). There are the usual chemical laboratory facilities and services, which are run in ducts along the external walls of the laboratories with access for further connexions. A feature is the storage of gas cylinders on the ground floor for easy access, oxygen, nitrogen and air passing to various points in the laboratories. The divisions between the pairs of large laboratories on each floor are formed with demountable partitioning to allow for future alterations if required. The working area has been considerably increased by designing the upper floors so that corridors have been almost eliminated.

An extension of the ground-floor area to the side of the old building includes a large room (800 sq. ft.)

intended for paint application and related studies, while the sub-basement comprises, in addition to a library stock room, additional staff facilities, storage and service rooms.

After the opening ceremony, and for the remainder of the week, the entire Station was open to view. More than six hundred people used the opportunity to inspect the wide range of exhibits covering every aspect of the work of the Station.

The main displays in the physics section were of studies on electron microscopy, colour perception and measurement, adhesion, and accelerated weathering. The numerous striking electron micrographs of pigment particles and the sections of paint films aroused much interest, as did the many intriguing displays illustrating the physiological basis of colour perception. Methods of precise colour measurement, and their application to problems of colour matching, including practical field tests on industrial colour matches, were shown. Various methods of measuring adhesion, including the direct pull-off technique used at the Paint Research Station, were shown, together with results on the effects of the composition of paint and exposure to moisture vapour and water. Correlations (both positive and negative!) between natural and accelerated weathering for various types of paint films were displayed.

Physicochemical studies were centred mainly on the surface chemistry of pigments, although there were several examples of polymerization reactions, for example, the polymerization of organo-metallic systems and the formation of graft copolymers. Techniques for measuring particle size and shape figure largely in current activities, and examples of the use of these to elucidate such problems as the effect on pigment particles of micronizing were exhibited. Adhesion tension measurements, adsorption studies of polar substances on pigment particles, surface-active agents, radiochemical tracer techniques, electrode potential measurements on paint films—all these physicochemical techniques and many more were on show and served to demonstrate the range and depth of techniques currently used in studies on paint.

Such fundamental investigations are linked directly with practical issues such as milling studies, the protective action of paint films against corrosion, and the effect of atmospheric pollution on paint durability and staining. In the technical laboratories, work on these factors was prominently displayed, together with other features such as the relation between viscosity of a liquid paint film and brushability and how the porosity of a substrate affects the adhesion of the paint film.

The work of the organic chemistry section is naturally concentrated on the media used in paints, that is, the synthetic polymeric resins used as film-formers. Current technological interest in water-based finishes, whether of the solution or emulsion type, was reflected in numerous exhibits. Water-soluble resins present special difficulties, because the films formed therefrom have afterwards to be water-

resistant; the chemical features controlling such factors were illustrated. Practical studies were again included; for example, the effect on the wet abrasion resistance of emulsion paint films of using volatile coalescent agents to replace partially the plasticizer. Detailed studies of the structure and analysis of alkyd resins, carried out over the past few years, were comprehensively surveyed. Media incorporating drying oils suffer from a tendency to yellow; some of the factors influencing this tendency, such as the catalytic action of organic bases and the chemical reactions involved, have been uncovered.

As might be expected from the wide range of materials used in paint manufacture, the work of the analytical laboratory has to cover an extremely wide field. Work on display included analytical schemes for white pigments and protective colloids, the application (sometimes in modified form) of standard

techniques, for example, chromatography, to problems of paint analysis and the special micro techniques developed to study paint blemishes and defects.

The growing interest in microbiological studies on paint has been reflected, as already described, in the provision of a special laboratory in the Jordan Laboratory. The display concerned identification of the various moulds, fungi or algae responsible for defects and assessments of the protective action of various chemicals against such microbiological attack. Special features appertaining to exposure under tropical conditions were also shown.

It is impossible in an article of this length even to list all the exhibits; the above will have indicated, however, the fascinating problems involved in paint manufacture and application, and the progress made at one research centre dedicated to their study.

L. VALENTINE

SELECTION AND TRAINING OF COMPUTER PROGRAMMERS

A SESSION of Sub-section A* (Mathematics) of the British Association at the recent Cardiff meeting was devoted to consideration of the selection and training of computer programmers. It took the form of an introduction followed by three short lectures and a very brief general discussion.

Introducing the subject, Dr. J. Howlett (Atomic Energy Research Establishment, Harwell) said that the electronic computer, although almost a household word, is really very new. Its rate of development has been remarkable, and it has put into our hands great and rapidly increasing logical and arithmetical powers; the use of computers is spreading widely in all fields, scientific and otherwise, but it is unlikely that their powers are yet fully appreciated or that the real nature of the task of programming them is completely understood. It is, therefore, only to be expected that there are sharp differences of opinion about the use and organization of computers and the types of person to be employed in connexion with them, how to select these people and how to train them.

When setting up a Computing Group, two important questions have to be settled: the relations with the establishment it serves, and the amount of stratification of the work within the Group. The first means deciding towards which of two extremes the Group shall tend: towards 'closed shop' working in which only the members of the Computer Group write programmes, or towards 'open shop' when anyone who wishes to do so may write his own programmes. The second concerns the extent to which the different kinds of tasks involved in going from the problem expressed in, say, the language of physics to a computer programme shall be performed by different people; these steps are formal mathematical analysis, numerical analysis, planning the flow or general structure of the programme and, finally, the detailed coding. The different tasks make quite different demands, and so if there is to be much division of labour, staff of several different types will be needed. Dr. Howlett suggested that scientific establishments tend to favour 'open shop' working and little stratification, while the reverse applies to commercial organizations and computer units tied to

large engineering enterprises; and that the latter are more inclined than the former to use selection methods based on formal aptitude and psychological tests. Finally, he referred to the recent developments in efficient automatic programming systems which make it reasonably easy for the non-specialist to write the programmes to do his own work; in many computer units this has resulted in much work being put on to the machine by people who could not be called programmers at all. This possibility has been brought about by the production of more powerful machines in the past few years and is certain to continue as computer power and the appreciation of this increases.

Mr. J. J. Foody (Short Bros. and Harland, Ltd., Belfast) described the experience and practice in his own Company, the field of which is aircraft engineering. Its computer unit in Belfast uses an English Electric *Deuce*. The staff is grouped into three classes: systems analysts, programmers and operators. The first are honours graduates who do all the essential mathematical work on the problems, taking the development to the stage where it can be used directly as the basis of a computer programme. Those in the second group are generally of pass-degree standing; they take over the work of the analysts and turn it into a programme, doing all the work of flow-charting, coding and testing. The operators (for card punching and machine running) need have no academic qualifications; Mr. Foody said they had at one time tried to use pass-degree people as operators, but the results were unsatisfactory. This led the Company to adopt the principle of looking for the lowest grade of staff capable of doing any particular type of work—over-qualified people become dissatisfied and look for a change. Programmers should have the ability both to see the essentials of a problem and to attack it in a logical and orderly manner; the Company therefore uses in its selection process problems intended to test these qualities, as for example variations on the classical coin-weighing problem, questions on the connexions for a simple circuit or the analysis of some familiar numerical process such as the digit-by-digit method for extracting a square root. Experience in recruiting young people has suggested that failure to grasp fundamentals is often

a fault of the teaching rather than of the person. Mr. Foody commented that the search for suitable staff had been made difficult by the shortage of mathematicians, particularly numerical analysts, in Northern Ireland.

For training, new recruits are given first an introduction to the kind of work done in the computing group, which covers a very wide range; this is followed by instruction in the simpler techniques of programming, and they are then left for about two weeks to study the programme manual, working out examples so far as possible on their own. After this they are taught more about the logical structure of programmes, with particular emphasis on the ideas of loops and sub-routines and from then onwards take up progressively more difficult 'live' work. A lot of emphasis is put on the need to keep proper records of all work done and the importance of neat and orderly paper-work. Mr. Foody concluded by saying that he considers the quality of management to be of vital importance in a computing group. Good management will not only ensure that the group is well organized and run, but also that the power and value of high-speed computation are made clear to all those who might benefit.

Mr. P. V. Ellis (International Computers and Tabulators, Ltd.) described the method of selection and training used in his Company, which makes computing, data processing and accounting machinery on a large scale. Programming to them means a wide range of activities, including service to customers to help with the use of existing machines, provision of assembly, interpretative and related programmes, detailed appraisal of projected machines in advance of any construction and assistance in the logical design of new machines.

Primary selection is made by interview and formal aptitude tests. A candidate successful at this stage embarks on a training course, but may at any stage of this be declared unsuccessful if it has become clear that he is not going to reach the required standard. The tests, the form of which has been evolved over several years, are administered by a professional organization; they do not call on factual knowledge, but are intended to test observational powers and

ability to think quickly and logically. They include problems in arithmetic, in the detection of faults in statements, in the application of selection rules, in logical inference and in logical deduction from sets of statements. Existing staff are used as a control, and Mr. Ellis said that the distribution of scores is satisfactorily stable. Candidates are assessed objectively by these tests and subjectively by personal interviews held before the results of the tests are known; agreement is usually good, and if there is any disagreement it is the usual practice to reject the candidate.

Training starts with a residential course lasting five weeks, new people being taken on in groups so that a class of ten or so can be formed. There are lectures, written papers and various co-operative activities. Those who complete the course satisfactorily move into different groups in the Company and continue training on 'live' work, each with an experienced member of the staff as mentor until they can stand on their own feet. The Company considers that the contacts made during the training course are of very great value in helping new people to acclimatize themselves to their new environment and to gain confidence.

Mr. H. Devonald (Ferranti, Ltd.) said that the comments he had heard during the interval suggested to him that many in the audience were unfamiliar with the ideas of programming and that he proposed, therefore, instead of further accounts of selection and training methods, to explain the essential points by means of a simple example. He then showed how one constructed a programme to solve a general quadratic equation, reading the coefficients from tape and printing the roots; he used the notation of the *Pegasus* auto-code.

In the brief discussion which closed the meeting, the principal speaker was Dr. A. D. Booth (Birkbeck College, University of London), who emphasized the importance of a constant mathematical awareness in all computing work. He instanced the difficulties one can get into by attempting to solve a partial differential equation by finite-difference methods without having a proper understanding of the mathematics of the process.

J. HOWLETT

PHYSICAL CHEMISTRY OF AEROSOLS

AIRBORNE clouds of small particles, or aerosols, are so widespread in Nature and arise in so many phases of modern industry that their study brings together a large group of physicists, chemists, meteorologists and engineers, each, of course, with his own special interests but all concerned with the generation, dispersion, sampling, counting, sizing, structure, composition, growth and aggregation of small particles. Such a heterogeneous ensemble aggregated in Bristol during September 13-15 to sample twenty-four well-dispersed papers at a discussion arranged by the Faraday Society, under the chairmanship of its president, Sir Harry Melville.

Broadly, there were four main topics for discussion: the nucleation of liquid and solid particles from the vapour phase; the coalescence, growth, evaporation and stabilization of liquid droplets; chemical reactions involving aerosols; and light-scattering by aerosols.

After some introductory remarks by Dr. R. Lessing, the symposium opened with a review by Dr. J. W. Dunning (University of Bristol) of the Volmer-Becker-Döring theory of homogeneous condensation and of various experimental studies of the phenomenon. Dr. Dunning was of the opinion that the results of expansion-chamber experiments had provided acceptable confirmation of the theory, but that condensation in expanding jets provided a more convenient and reliable technique of investigation.

Dr. B. J. Mason (Imperial College of Science and Technology, London) described some recent studies of homogeneous and heterogeneous nucleation of water aerosols involving vapour-liquid, supercooled liquid-solid and vapour-solid transitions. He underlined the limitations of the Volmer theory of homogeneous condensation and did not consider that this had been adequately tested and confirmed by experiment. He next discussed the growth of water droplets

on ions and on hygroscopic nuclei and their relevance to cloud physics. There followed a description of his recent work on heterogeneous and homogeneous nucleation of supercooled water droplets, of the efficiency of natural and artificial ice nuclei in relation to their crystalline and surface structure, and of the formation of ice crystals by direct sublimation from the vapour.

Dr. N. H. Fletcher (University of New England, New South Wales) had applied the Volmer theory of heterogeneous nucleation to calculate the conditions under which ice nuclei would form on a perfect spherical particle. Curves were presented showing the temperatures at which nuclei could be expected to form at the rate of one per second in a water-saturated atmosphere on particles of various radii and forming various angles of contact with the ice embryo. These results were then used to calculate the maximum number of silver iodide nuclei produced from 1 gm. of the material which would be active at various temperatures. In the discussion which followed, doubt was expressed concerning the validity of this treatment, which did not recognize that nucleation of ice on silver iodide and other substances occurs preferentially at surface imperfections.

Phase changes involving salt-vapours were the subject of a paper by Dr. E. R. Buckle (Imperial College of Science and Technology, London), who described his observations of condensation, growth and evaporation of liquid and solid particles of alkali halides in a high-temperature cloud chamber. It appears that for a wide variety of substances (for example, metals, ionic salts, water) condensing and crystallizing homogeneously, the maximum attainable degree of supercooling is almost exactly 15 per cent of the melting temperature. Interesting information on the structure and growth of particles formed by the vaporization of metals in air was provided by the electron- and X-ray diffraction and electron microscopy work of J. Harvey, H. I. Matthews and H. Wilman (Imperial College of Science and Technology, London).

In the final paper bearing on nucleation phenomena, Prof. F. P. Buff (University of Rochester, N.Y.) examined, from the point of view of molecular hydrostatics, the Gibbs theory of capillarity which calculates the higher terms in the asymptotic expansion of the free energy with respect to the geometrical parameters of the system, and provides a criterion for the breakdown of macroscopic thermodynamical concepts for small aggregates of molecules. In Buff's analysis there appear two tensions rather than a single surface free energy, and he argues that Gibbs's formulation is correct only in the (practically important) case when these two tensions are equal.

In the next group of papers, dealing with the growth, evaporation and coalescence of drops, Dr. D. P. Benton (Battersea College of Technology, London) and Dr. G. A. H. Elton (British Baking Industries Research Association, Chorleywood, Herts) presented experimental evidence for coalescence between micron-size water droplets colliding in highly turbulent air being affected by the addition of electrolytes and ionic surface-active agents to the water. The hypothesis is that these modify the structure of the surface electrical double layer, the existence of which is normally a barrier to the coalescence of two colliding drops. Discussion centred on the importance of this for the stability of non-turbulent water fogs where hydrodynamic forces

prevent collisions between such small droplets, and on whether an appreciable electrical field would exist outside the surface double layer.

Dr. R. M. Schotland (New York University) had carried out experimental work on the coalescence of falling drops, 200–800 μ in diameter, with large liquid hemispherical targets. He claimed that the coalescence mechanism was governed by two dimensionless parameters which, surprisingly, did not include the viscosity of the fluid separating the two liquid surfaces.

Measurements of the growth-rate of water droplets condensing on hygroscopic nuclei as a function of the humidity, temperature and velocity of the surrounding air stream were described by Dr. W. L. Dennis (Chemical Defence Experimental Establishment, Porton Down). Experimental results for drops of 0.3–1.0 mm. diameter agreed within about 20 per cent, with theoretical values derived from the standard equations for the growth of ventilated drops containing dissolved salts.

A remarkable experiment designed to measure the long-range diffusive forces between water drops and solid particles was described in a paper by Prof. P. S. Prokhorov and L. F. Leonov (U.S.S.R. Academy of Sciences, Moscow). The authors claim to have measured repulsive forces of order 10^{-4} dyne between a 1-mm. evaporating water drop and a glass sphere of similar size attached to one arm of a torsion balance, and to have shown that the magnitude of the force varies inversely as the square of the distance between them.

The influence of a foreign surface film on the evaporation of liquid drops, in particular its effect on the condensation coefficient, was discussed theoretically in papers by Prof. B. V. Derjaguin, S. P. Bakanov and I. S. Kurghin (U.S.S.R. Academy of Sciences, Moscow) and by Dr. P. G. Wright (University of St. Andrews). Some measurements on the stabilization of water mists containing droplets of 2–20 μ radius by insoluble monolayers were presented by Dr. H. S. Eisner, B. W. Quince and C. Slack (Safety in Mines Research Establishment, Buxton). The addition of about 0.1 per cent of fatty alcohols to the water increased the lifetime of the drops several hundredfold.

The importance of aerosols in catalysing chemical reactions in the atmosphere was brought out in two papers. Dr. R. D. Cadle and Dr. R. C. Robbins (Stanford Research Institute, California) had applied chemical kinetic theory to calculate the rates of heterogeneous chemical reactions involving aerosols, and compared the theory with experimental results for the systems nitrogen + ammonia + sulphuric acid and air + water + nitrogen dioxide + sodium chloride. A. C. Chamberlain, Dr. A. E. J. Eggleston, W. J. Megaw and J. B. Morris (Atomic Energy Research Establishment, Harwell) had investigated the rate at which radioactive iodine vapour in concentrations of less than 1 $\mu\text{gm./m.}^3$ was adsorbed on atmospheric nuclei, and demonstrated that this must be allowed for in the design of systems for removing radioactive iodine from reactor shells.

The next three papers, on light scattering by aerosols, provoked a lively discussion. E. Matijević, Prof. M. Kerker and K. F. Schulz (Clarkson College of Technology, New York) described how, using silver chloride aerosols, they had obtained excellent agreement between the polarization ratio from light-scattering measurements and that calculated from

the particle-size distribution and theoretical scattering functions. Since the light-scattering itself was insensitive to particle-size distribution over the range studied ($r = 200\text{--}800\text{ m}\mu$) the particle size could not be determined from light scattering, but there was an optimum size-range around $55\text{ m}\mu$ for which this was possible. Prof. F. K. Gucker and R. L. Rowell (Indiana University) had succeeded in determining the light-scattering diagrams of single aerosol droplets by first charging and suspending them in an electric field, illuminating them with monochromatic light and measuring the light scattered into a photometer over the arc $40\text{--}140^\circ$ from the direction of illumination. Good agreement was obtained with calculations based on the Mie theory. The effect of particle separation on the light-scattering properties of monodispersed spheres was investigated by Prof. S. W. Churchill (University of Michigan), G. C. Clark (Continental Oil Co., Ponca City, Oklahoma) and C. M. Sliepcevich (University of Oklahoma) by meas-

uring the transmission of light through a hydrosol of latex spheres as a function of the particle concentration. According to their measurements, optical interference between the particles is negligible when their average separation exceeds 1.7 particle diameters.

The wide scope of the conference was epitomized in the last two papers, representing meteorology and fuel technology. Dr. C. L. Hosler and Dr. R. E. Hallgren (Pennsylvania State University) described how the aggregation of small ice crystals was affected by their shape, and particularly by the air temperature; Dr. R. H. Essenhigh and Dr. I. Fells (University of Sheffield) presented a mathematical theory of the combustion of liquid and solid aerosols.

The conference enjoyed the generous hospitality of the University of Bristol and the excellent facilities of the new Queen's Building. One's main regret was that the Russian contributors were not there to present and discuss their four papers. B. J. MASON

PHYSICS OF SEMICONDUCTORS

AN international conference on the physics of semiconductors, sponsored by the International Union of Pure and Applied Physics and arranged by the Czechoslovak Academy of Sciences, was held in Prague during August 29–September 2. In recent years this has become a biennial conference, the previous one having been held in Rochester, New York (*Nature*, 108, 1067; 1958), in August 1958, and it is proposed that the next of the series should be in Britain in 1962. The present conference showed clearly that semiconductor physics still represents a very active and indeed an expanding field of research. It is, of course, unwise to judge only by the numbers of papers submitted or by the number of physicists attending the conference; but this gives some indication, and was supported by the fact that new ideas emerged and many new and exciting developments were reported. Indeed, the chief problem which had to be faced by the organizers was that of selecting from the large number of papers submitted. Approximately 265 papers were selected for inclusion in the conference proceedings, of which only about half were actually read. The geographical division of these papers is of some interest; approximately 110 originated in the United States, 40 in the U.S.S.R., 22 in Germany, 20 in Great Britain, 15 in France, 14 in Czechoslovakia, 9 in Poland and 7 in Japan, the remainder being distributed over a large number of participating nations.

The number of physicists attending was much larger than for any previous conference of the series, being nearly 750. As a result, it was necessary to divide the conference into four parallel sessions, three of which were run on the normal pattern of papers followed by discussions and one using *rapporteurs* followed by discussion. In the former, translations into Russian, Czech and English were available, though the English translations were frequently very difficult to follow. The chief drawbacks of the conference arose from its large size, there being many overlapping papers of interest, and it is hoped that future conferences will revert to a smaller and more intimate form.

It is impossible in the space available even to mention all the interesting topics discussed at the conference, and only a few of the highlights can be selected that left the most vivid impressions in the memory. Introductory papers were given by (the late) A. F. Joffe and by W. Shockley. The former stressed the urgent need for a new theoretical approach to the problem of low-mobility semiconductors for which conventional theory based on a nearly perfect crystalline lattice is clearly inapplicable, the mean free path for current carriers being comparable with the lattice spacing. Various discussions based on 'electron hopping' were later given; but it is clear that a lot more work is required before these processes are as well understood as transport phenomena in high-mobility semiconductors. Later in the conference Joffé discussed some of the difficulties associated with the understanding of thermo-electric phenomena in semiconductors. In his introductory paper Shockley discussed a wide variety of phenomena associated with avalanche breakdown in $p\text{--}n$ junctions induced by high electric fields, and introduced some new theoretical ideas which might lead to a better understanding of these complex phenomena.

Discussion of transport phenomena again dominated the conference, there being no less than 48 papers submitted on this subject, dealing mostly with silicon and germanium, which remain the basic semiconductors for the study of fundamental phenomena. C. Herring (United States) reviewed developments in the theoretical formulation since the Rochester conference and directed attention to some recent clarification of the difficult problems associated with multi-phonon scattering, and of scattering of carriers in the presence of strong magnetic fields. Two interesting new experiments on transport stood out. The first was described by W. Shockley and K. Hubner (United States) in which an $n\text{--}p\text{--}n$ structure was used to demonstrate phonon drag on electrons. Some electrons given momentum by an electric field applied in one n -type region pass into the p -type region where they are scattered, producing phonons with a preponderance of momentum in

the same direction; these diffuse into the second *n*-type region producing an observable e.m.f. through making collisions with electrons. The second experiment, described by T. P. McLean and E. G. S. Paige (Great Britain), consisted of demonstrating by means of measurements of drift mobility at low temperatures an important drag effect of the majority carriers on the minority carriers. A number of papers dealt with the variation of mobility with temperature and it was clear that in spite of the large amount of work carried out in this field there are still aspects of it which are not properly understood. A considerable number of papers dealt with 'hot' electrons produced by strong electric fields.

Perhaps the outstanding new development reported at the conference was the use of the phenomenon of quantum-mechanical tunnelling, discovered by L. Esaki, as a tool for the study of some of the fundamental properties of semiconductors. By a combination of theory with the study of the voltage-current characteristics of 'tunnel' diodes, it was shown by R. N. Hall (United States) that much valuable information may be obtained on the phonon energies associated with the band edges of semiconductors such as germanium, and also possibly on polarons in partially polar semiconductors such as the 3-5 compounds. There was, however, some doubt cast, particularly by E. O. Kane (United States), on some aspects of the interpretation of the experimental data.

The optical properties of semiconductors again gave rise to a considerable number of papers (45 if we include photoconductivity), and, as at Rochester, a discussion of excitons played a prominent part. The experiments of S. Nikitine (France) and of E. F. Gross and his colleagues (U.S.S.R.), particularly with cuprous oxide, seem now to be well understood in terms of the theory of R. J. Elliott (Great Britain), an excellent example of international co-operation. The paper by Gross and his colleagues stressed, however, that there is still no convincing direct evidence for exciton transport though its deduction from theory is beyond doubt. They described various optical effects which they have observed in cuprous oxide and which are a consequence of the fact that an exciton is free to move. (The form of the exciton spectra in indirect transitions in germanium and silicon reported at Rochester are also a consequence of the freedom of the exciton to move.) Optical effects in magnetic fields discussed by B. Lax (United States) and others have continued to provide a powerful tool for the investigation of the band structure of semiconductors. Work on the

lattice vibrational spectrum of semiconductors is becoming of first importance, and interesting new results were reported by F. A. Johnson (Great Britain). In particular it is of considerable theoretical interest that the *T.A.* mode in 3-5 compounds such as indium antimonide has a low energy at the zone edge as for silicon and germanium. Surprising new effects in the absorption associated with the *reststrahl* band in gallium arsenide were also reported by Johnson. Emission of radiation due to inter-band transitions with various phonon combinations reported for silicon by J. R. Haynes, B. Lax and W. F. Flood (United States) and for germanium by Benoît & la Guillaume and O. Parodi (France) threw new light on these processes, especially when taking place by means of an impurity centre, and also provided very accurate values for various energies associated with the phonon spectrum. Further information on the band structure of germanium-silicon alloys and of a number of 3-5 compounds was obtained from the accurate measurement by J. Tauc (Czechoslovakia) of optical reflectivity in the visible and near ultra-violet regions of the spectrum. In particular, fine structure was observed which could be interpreted as due to the spin-orbit splitting of the valence band at the zone edge. At the other extreme, photoconductivity was reported in indium antimonide in a magnetic field at 1.7° K., by R. A. Smith (Great Britain), extending throughout the far infra-red spectrum to wave-lengths beyond 2,000μ.

A considerable number of papers was devoted to the study of ionic crystals and this widened considerably the scope of the conference. In the sessions on new materials, the 3-5 compounds received a good deal of attention, but organic semiconductors were also discussed by C. G. B. Garrett (United States) and an interesting group of defect compounds such as In_2Te_3 by V. P. Zuzue and his colleagues (U.S.S.R.).

Perhaps the most mysterious phenomenon discussed without reaching a satisfactory explanation was the occurrence of oscillations in *n*-type germanium and indium antimonide carrying a current in a longitudinal magnetic field. These appear to be due to plasma effects and were described by P. Aigrain (France) in terms of 'helicons'. Such topics for argument gave spice to what was in any event a very stimulating and thought-provoking conference, which was concluded by an excellent summary of the highlights by J. Tauc. This summary was of the greatest help in preparing this report. The conference papers will be published by the Czechoslovak Academy of Sciences in due course.

R. A. SMITH

ERGONOMICS IN INDUSTRY

A CONFERENCE on ergonomics in industry, organized by the Department of Scientific and Industrial Research, was held in the Connaught Rooms, Great Queen Street, London, during September 27-29. It was attended by more than three hundred representatives of some two hundred industrial firms. The purpose of the conference was to explain the features of ergonomics, to describe some of the ways in which it has already been applied to industry, and to discuss the possible ways in which

further use of ergonomic techniques and ideas could be promoted.

Sir Harry Jephcott, chairman of the Council for Scientific and Industrial Research, introducing Lord Hailsham, Minister for Science, who formally opened the conference, said that it was the logical development of a meeting held in March 1959 in Zurich organized by the European Productivity Agency, and entitled "Fitting the Job to the Worker". At Zurich there were three groups, representing manage-

ment, trade unions and research workers. In the present conference, he said, industry had provided by far the largest group, although the trade unions were also represented. The research workers were there to present papers and to answer questions, but it was not primarily a scientific congress with discussion between scientists; the scientists' job was to tell their story, and the industrialists on their side were required to comment and to criticize, to try to find out how far the findings and the ideas of the research workers were useful or potentially useful to the industrialists.

In addition to a series of papers, there was a number of exhibits demonstrating application in particular fields provided by the Medical Research Council, General Post Office and several research associations and centres of the Department of Scientific and Industrial Research, notably the British Iron and Steel Research Association, the British Boot, Shoe and Allied Trades Research Association, the Road Research Laboratory, and the Building Research Station. An exhibit on seating had been arranged by the Physiological, Anatomical, British Psychological and the Ergonomics Research Societies, together with the Furniture Development Council.

The papers at the conference were presented under the headings of "What Ergonomics Means", "The Place of Ergonomics in Industry", "Ergonomics and Production", "Ergonomics in the Post Office and in the Steel Industry", "Ergonomics and Products" and the "Future of Ergonomics".

The term 'ergonomics' means the study of the laws of work, and more specifically the study of the relationships between the worker and his environment. Such a study embraces a very wide field, and involves research derived mainly from physiological, psychological and anatomical studies. Up to the present, the Armed Forces have provided the chief field of study, although the term 'personnel research' has been used to describe the work. Although many of the problems affecting the worker can be described as primarily physiological, such as extremes of heat or cold, or psychological (namely, the presentation of information), or anatomical (namely, the anthropometric data required to design a work space), there are very few cases in which a single-discipline study is adequate. This means that a multi-disciplinary approach is necessary, and the techniques and methods required to develop such an approach are one of the basic problems of ergonomics. However, the problem does not end at this point, since it is clear that engineering aspects are equally important. Without a knowledge of the engineering problems involved, a solution can be put forward which is either impracticable or exceedingly expensive. At the conference a number of speakers, both in presenting papers and in discussions following papers, emphasized the need to view the problem and its proposed solution in the total setting of industry, that is, to include the worker relationship and trade union views, management and economic aspects. It was generally agreed that there is a need to bring biology into industry, but this requires that a proportion of engineers, especially those concerned with the design of equipment, and production engineers, should have some undergraduate instruction in biology. Equally, biologists require a knowledge and understanding of the complex nature of industrial problems.

Dr. A. Y. Wisner, who is head of the Physiological Section of the Renault Factory in France, illustrated many of these points. He has had to become familiar with the problems of design of motor-cars, with the engineering and production difficulties involved, as well as the economic aspects. He regards himself as an adviser who must not overlook the fact that important and decisive design or economic consideration must have their place in considering requirements for the comfort and safety of the driver. Furthermore, unless the biologist is involved at the beginning of a design study, it is unlikely that he can make a useful contribution, as even apparently small alterations in, for example, the position and angling of pedals can involve expensive re-tooling and extensive re-design.

The importance of engineering was also brought out in a paper by Mr. W. T. Singleton, who was until recently head of the Ergonomics Department of the British Boot, Shoe and Allied Trades Research Association. The sewing machines used in the shoe industry have a simple mechanism for starting and stopping, using a clutch and a continuously rotating fly-wheel. This type has been in use for fifty years or more; but details of the operator's work have changed, becoming in general more complicated. Experiments showed that this form of power transmission is not suitable for producing controlled speeds other than the maximum, and with the more complex tasks the machinists could not always stitch at maximum speed. This apparent paradox was solved by the skill of the machinist in achieving slower than maximum speeds by flicking the clutch on and off at about 3 cycles/sec. The skill required to do this to produce a particular speed was considerable and took time to learn. A variable-speed power transmitter was required, and this needed considerable engineering development before it could be produced in large numbers. A laboratory model was made and a comparison made with the standard machine. The results showed that operators with no machinery experience performed better using the variable-speed control than did skilled machinists using the orthodox control. In the factory there was an improvement in speed of 10-15 per cent. This information made it possible to calculate the financial benefit of the new system, an essential factor, as there are about 100,000 machines of this type in Britain. The improvement was clearly worth while, and hence it was considered justifiable to embark on the engineering study needed to produce a new machine.

Three industries in which ergonomics already plays a considerable part are the General Post Office, London Transport and the steel industry. Papers were given describing the effects of heat in a steel mill, essentially radiant heat which, as Dr. R. F. Hellon said, cannot be cured by ventilation, as one cannot blow away radiation. There are three ways in which a severe heat situation can be combated: by reducing the level of work so that heat-loss balances heat-production, or by working at a normal rate and taking frequent rests to cool off, or by reducing heat stress so that normal working is not impeded. The last is clearly the desirable method, but the usual practice in industry is to combine the first and second. Dr. Hellon then outlined possible ways of relieving the heat stress.

Dr. L. G. Norman described the way in which the cab of the new 'Route Master' bus has been designed by a team which included medical officers, trade

unionists and engineers. Others joined the team at different times to advise on seating, ventilation, position of controls and the muscular forces required to operate them. Among the problems was the lack of anthropometric data relating to bus drivers, so calculations had to be based on published measurements of National Service recruits. The need to increase the range of anthropometric data was stressed by other speakers, including Dr. J. S. Weiner, assistant director of the Medical Research Council's Unit on Climate and Working Efficiency.

The discussion after the papers was in general lively, and there were many useful criticisms. The now

familiar problem of communication was frequently mentioned as one of the reasons for the delay in applying biological research to industry. The biologists were advised that industry must not be led to expect that solutions to all its problems are within immediate grasp, and the industrialist was advised that research workers are not good salesmen, but that did not mean they did not have valuable services to offer.

There is, therefore, a strong probability that there will be a considerable demand from industry for biologists and biological advice. The difficulty will be in supply.

O. G. EDHOLM

ULTRACENTRIFUGATION OF BIOLOGICAL MACROMOLECULES

THERE were about a hundred participants from several countries at the informal meeting on ultracentrifugation organized on behalf of the Faraday Society at Birmingham during September 14-15. Prof. K. O. Pedersen (Uppsala) gave a stimulating historical introduction. Papers by Dr. J. M. Creeth (Lister Institute, London) and Dr. H. G. Elias (Zurich) considered thermodynamical aspects of the sedimentation of multicomponent systems, while Dr. M. Gehatia (Frankfurt am Main) discussed various methods of evaluating S and D constants from the shape of the gradient curve of ultracentrifugation. Dr. G. A. Gilbert (Birmingham) described his theory concerning the analysis of moving boundaries in reversibly aggregating systems; examples of its application being provided in papers by Drs. S. N. Timasheff and R. Townend (Philadelphia) and by Mr. K. A. Cammack (Medical Research Establishment, Porton). A paper by Drs. A. J. Rowe and Dr. P. Johnson (Cambridge) considered the interaction of actin and myosin by ultracentrifugal studies.

Dr. P. A. Charlwood (Medical Research Council, Mill Hill) reviewed trends in the determination of molecular weights of macromolecules from transient state measurements in the ultracentrifuge and Dr. H. G. Elias (Zurich) discussed the various methods of determining the experimental values used in the Archibald expression. Dr. G. Träxler (Munich) con-

sidered various ways of using the analytical ultracentrifuge in the measurement of diffusion constants of macromolecules. Papers on the sedimentation of charged macromolecules were presented by Prof. K. O. Pedersen and Dr. R. G. Wallis (Medical Research Establishment, Porton).

A new recording device for the ultra-violet absorption was discussed by Drs. J. B. Th'Aten and A. Schouten (Rijswijk, Netherlands), while Dr. I. Wiedmann (Basle) described a new schlieren optical system. Drs. P. A. Bianchi and K. V. Shooter (Chester Beatty Institute, London) considered the study of the sedimentation characteristics of deoxyribonucleic acid by the ultra-violet system.

Application of zone-centrifugation to the analysis of human serum proteins was described by Dr. D. R. Stanworth, Prof. J. R. Squire and Mr. K. James (Birmingham). Drs. P. Johnson and A. Albert discussed the sedimentation characteristics of human serum macroglobulins.

A suggestion by Prof. K. O. Pedersen that sedimentation coefficients should be referred to 25° C. rather than 20° C., as is becoming the practice in the United States, evoked considerable discussion, but no final decision was taken.

Prof. K. O. Pedersen, Dr. A. S. McFarlane (Medical Research Council, Mill Hill) and Dr. R. A. Kekwick acted as chairmen and Dr. P. Johnson summed-up at the end of the proceedings. D. R. STANWORTH

MIGRATION OF MARINE ORGANISMS

A LATIN American symposium on migration of marine organisms was held at Guayaquil, Ecuador, from June 27 until July 1. It was organized jointly by the Unesco Science Co-operation Office for Latin America and the University of Guayaquil.

It was the fifth of the series of meetings on marine sciences which the Office has held since its foundation in 1949. The previous meetings had, like the Guayaquil one, the double character of symposium and working-party session. They were held at Concepción, Chile, in 1954; São Paulo, Brazil, in 1955; Montemar, Chile, in 1956; and Montevideo in 1957.

Dr. Enrique Rioja (Mexico) was elected chairman of the symposium and Dr. Hugo Ferrando (Uruguay) acted as secretary. Thirteen marine scientists parti-

cipated, from the following countries: Argentina, Brazil, Chile, Cuba, Ecuador, Mexico, Peru, Uruguay. The Unesco Science Co-operation Office for Latin America was represented by Dr. Angel Establier.

The programme of the meeting was as follows: (1) migration of marine organisms, namely (a) fish, (b) invertebrates, (c) cephalopods, (d) birds, (e) other vertebrates; (2) study of environmental factors causing migration, (a) oceanographic factors, (b) biological factors; (3) standardization of methods for studying migratory phenomena, with the view of comparing results; (4) establishment of regional programmes for work on migration of aquatic populations; (5) general discussion of other problems related to migration of marine organisms.

At the conclusion of the symposium, six recommendations were unanimously approved by the participants. First, considering that the study of the migration of marine organisms by its very nature requires a joint effort on the part of the countries concerned, regional action was recommended. The following delimitation of problems common to a number of countries was made with a view to their being undertaken regionally: Argentina, Brazil and Uruguay: Thunnidae, Scombridae, Clupeidae (*Sardinella* sp.), Galeorhinidae (*Galeorhinus vitaminicus*) and Mugilidae (*Mugil* sp.); Chile and Argentina: Merlucoidea (*Merluccius* sp.), Decapoda (Macrura—"Langostinos"—Shrimps and "Langosta" de Juan Fernández); Peru and Chile: Thunnidae (*Neothunnus macropterus*), Engraulidae (*Engraulis* sp.), Scombroidea (*Sarda* sp.) and Decapoda (*Munda* sp.); Peru, Ecuador and Colombia: Thunnidae (*Katsuwonus* sp.) (*Neothunnus macropterus*), Decapoda (Macrura—"Langostinos"); Mexico, Caribbean and coast of Venezuela: Thunnidae (*Katsuwonus* sp., *Thunnus* sp.), Centropomidae (*Centropomus* sp.), Decapoda (Macrura—*Panulirus* sp. and Penaeidae—*Penaens* sp.).

Secondly, it was recommended that information be exchanged between Argentina and Chile covering research results and methods used in work on the

principal species of *Merluccius*. Thirdly, marking trials should be held in conjunction with studies on the biological cycle of the species (growth, reproduction, alimentation, etc.) with the view of relating migration and the different phases of life of individuals. Similarly, the importance of the study of environmental conditions emphasized at the meeting of the Unesco Marine Sciences Working Party, held at Montevideo during May 22–24, 1957, was underlined.

In view of the importance of movement and mixture of different bodies of water, it was expressly recommended that Argentina, Brazil and Uruguay should study the northern and southern limits and fluctuations respectively of subantarctic and subtropical waters and also the origin of the water of the coastal region. It was hoped that similar work might be undertaken for the south-east Pacific area in the fairly near future.

Unesco was also asked to interest the Governments of Latin America in helping this type of scientific work, which is an indispensable basis for a proper knowledge of the renewable resources of the sea. Finally, it was recommended that the next marine sciences meeting to be organized by the Unesco Latin American Science Co-operation Office should be divided into two sections: 'abiotic oceanography' and 'marine biology'.

ABSOLUTE DATING OF THE MIDDLE ORDOVICIAN

By PROF. J. A. S. ADAMS and J. K. OSMOND*

Department of Geology, William Marsh Rice University, Houston, Texas

AND

DR. G. EDWARDS and W. HENLE†

Shell Development Co., Houston, Texas

A NUMBER of recent papers have amply emphasized the need for absolute dating of geological samples which meet two essential requirements: (1) occupy an unambiguous position in the classical stratigraphic column; (2) contain unaltered mineral conducive to age determination by the well-established stable-isotope methods.

This communication presents additional results from our work^{1,2} on the dating of the Middle Ordovician and discusses the factors which must be considered when sufficient data become available to consider revision of existing geological time-scales.

Several years ago, G. Hamill³ made a petrographic and geochemical study of bentonites, particularly of the fine, euhedral zircon found in low concentrations (one part in 20,000–40,000). This work and the results of further experiments have consistently led to the belief that the zircon was indigenous to the volcanic ash falls which gave rise to the bentonite beds. The bentonites occur as beds in fossiliferous marine deposits, and hence their positions in the stratigraphic column are usually unambiguous, so that zircons in bentonite clearly offer an excellent possibility of ascribing absolute ages to the geological time-sequence of marine deposits.

The bentonites also contain biotite, generally in greater concentration than the zircon. In 1958 we published preliminary age determinations by the rubidium-strontium method on biotites of Devonian and Ordovician age which were later cited by K. I. Mayne, R. St. J. Lambert, and D. York⁴ in an article in which they proposed a much more radical revision of the Holmes time-scale than was suggested by our results. In our original publication, we stressed the fact that these measurements were of a preliminary nature and that the experimental error could probably be reduced by a study of the zircon in bentonites.

During the past year, samples of pure zircon and of zircon with small amounts of monazite and apatite, in quantities of about 1 gm., were obtained from several bentonites. Zircons from four bentonites were chosen for age determination because they occurred in relatively high concentration, and because the stratigraphic position of occurrence was well established⁵.

Microscopic examination showed that the zircons were euhedral, and none exhibited rounding of the crystal edges or overgrowths that would be inconsistent with a pyroclastic origin. The zircons were commonly associated with subhedral biotite flakes, euhedral apatite, sanidine and euhedral quartz. The appearance of the quartz was consistent with a high-temperature morphology (positive and negative rhombohedra with little or no development of prism

* Present address: Geology Department, Florida State University, Tallahassee, Florida.

† Present address: Shell Development Co., Emeryville, California.

faces). In no case was a mineral (for example, garnet or kyanite) observed that was inconsistent with a pyroclastic origin.

The results of isotope measurements on lead and the amount of uranium in the zircon from the Ordovician bentonites are shown in Table 1.

Table 1

Sample number, location, and stratigraphic position	Concentration* (10 ⁻⁶ gm./gm.) Pb U	Lead-isotopic composition (per cent)			
		204	206	207	208
GH-22 Alexandria, Tenn., Carters Limestone, Stones River group	34.5 320	0.387	64.680	9.585	25.347
GH-7 Vonore, Tenn., Bays Formation	29.7 814	0.277	70.762	8.239	20.722
GH-24 Dowelltown, Tenn., Carters Limestone, Stones River group	26.7 317	0.157	76.317	6.855	17.670
GH-17 Nashville, Tenn., Carters Limestone, Stones River group	27.2 335	0.219	72.220	7.896	20.165

* Lead and uranium by isotopic dilution

In all cases, the amount of common lead present as indicated by the presence of lead-204 was more than 11.5 per cent of the total. 1 gm. of zircon was used for each experiment, and repeated experiments have shown contamination by common lead in the laboratory to be consistently less than 0.8 μ gm. All the zircons contained more than 26 μ gm. lead, and hence the experimental contamination is thought to have contributed about one quarter of the common lead observed to be present in sample GH-24 and a lower fraction of the common lead in the other experiments. It is reasonable to assume that at least the major portion of the common lead observed was incorporated in the zircon at its time of crystallization.

On the basis of isotope data for oceanic lead by T. J. Chow and C. C. Patterson⁵ and with computation in the way described by C. B. Collins, R. D. Russell, and R. M. Farquhar⁶ for the rate of change of the lead isotopes with time, we estimate average ratios of the isotopes of common lead in Middle Ordovician time as:

204	206	207	208
1	18.260	15.675	38.490

Lead in sanidine present in the bentonites may ultimately yield more pertinent information than this approximation of the actual isotopic composition of common lead in these zircons.

The above estimates, together with the isotopic data of Table 1, were used as described by A. O. Nier, R. W. Thomson, and B. F. Murphey⁷ to obtain the ages shown in Table 2. Radioactive decay constants of 1.537×10^{-10} and 9.72×10^{-10} yr.⁻¹ were used for uranium-238 and uranium-235 respectively.

Table 2. ISOTOPIC AGES IN MILLION YEARS

Sample number	Uranium-238/lead-206	Uranium-235/lead-207
GH-22	452 $\pm$ 10	483 $\pm$ 20
GH-7	453 $\pm$ 10	471 $\pm$ 20
GH-24	446 $\pm$ 10	478 $\pm$ 20
GH-17	438 $\pm$ 10	452 $\pm$ 20

Subtraction of the isotopes of common lead from the measured isotope concentrations involves 4–11 per cent of the total 206 isotope and 36–64 per cent of the 207 isotope. The uranium-238/lead-206 ages are consequently less affected by the assumed common

lead isotope ratios than are the uranium-235/lead-207 ages. The discordance in ages based on uranium-238 and on uranium-235 may be accountable in this way, but may represent one of the forms of discordancy discussed by G. W. Wetherill⁸.

As is common, when the uranium-238/lead-206 age is not in close agreement with the uranium-235/lead-207 age, the lead-207/lead-206 age is still more discordant. In the absence of more accurate information on the composition of common lead in these zircons, we regard the uranium-238/lead-206 age as the best approximation of the mineral age.

Recently, H. Faul and G. R. Tilton carried out age measurements on zircon and biotite from a bentonite in Alabama beds which were stratigraphically very close to those of the Tennessee samples reported here. We are greatly indebted to them for permission to include their data (Table 3) in this article. The uranium-238/lead-206 age computed by them is within 0.5 per cent of the average of that for the Tennessee samples. In all respects their measurements are, within experimental limits, corroborative.

Shortly after the preliminary rubidium-87/strontium-87 ages referred to previously were published in 1958¹, several authors made use of these and other data to interpolate and extrapolate to other geological periods in an effort to establish substitutes for the Holmes scale. The premature proliferation of various time-scales is unfortunate, because it confuses the many persons who are interested in the results, but who are not conversant enough with all the geological and experimental details to choose among the various scales or to reject them all. These proposed scales all assign ages to the beginning of each geological period.

Samples suitable for age measurement seldom occur at the boundaries of the geological periods, and interpolations of the experimental data to yield period dates involves the additional uncertainty of estimating the rate of sedimentation in the various periods and localities. As more data become available, interpolation of boundary ages of the geological series will become more reliable. Of the data discussed here, we

regard the average of the consistent uranium-238/lead-206 ages (447 ± 10 m.y.) as the most reliable for the Middle Ordovician (Stones River and Bays formation) time in Tennessee and Alabama, for both experimental and stratigraphical reasons.

We are of the opinion that only after many measurements have been conducted on samples from the various geological periods and have proved to be consistent will it be prudent to try to devise a new geological age-scale.

Two of us (J. A. S. A. and J. K. O.) received financial support from the Robert A. Welch Foundation in all the geological and mineralogical aspects of this work. One of us (J. K. O.) received financial support from the Petroleum Research Fund of the American

Chemical Society. We repeat our indebtedness to Drs. H. Faul and G. R. Tilton for their permission to publish their results in this article.

OBSERVATIONS OF EARTH-IONOSPHERE CAVITY RESONANCES

By M. BALSER and C. A. WAGNER

Lincoln Laboratory*, Massachusetts Institute of Technology

IN 1952, Schumann^{1,2} published a detailed description of the resonant modes to be expected for the concentric spherical cavity bounded by the Earth and the lower region of the ionosphere. For such a cavity with perfectly conducting walls, the resonant frequencies should obey the relation:

$$f_n = f_1 \sqrt{\frac{n(n+1)}{2}} \quad (1)$$

with a fundamental-mode frequency $f_1 = 10.6$ c./s. to be expected for a cavity the size of the Earth.

The ionosphere is, however, a rather poor conductor, and it is furthermore quite difficult to estimate the losses to be expected for oscillations of these extremely low frequencies, because of the tremendously varying ionospheric conditions of electron density and collision frequency in the regions penetrated by the field³. These losses result in a relatively low value of Q (the ratio of resonant frequency to frequency separation of the half-power points) for the mode, and the question has been raised as to whether it is indeed so low that it would be difficult to measure the spectrum at all. Another effect of the low value of Q is a shift in the resonant frequency. A general result in the theory of resonant cavities⁴ gives:

$$f = f_0 \sqrt{1 - \frac{1}{Q}} \quad (2)$$

as an approximation to the peak frequency f of a mode which would have a resonant frequency f_0 in a perfectly conducting cavity. This expression would no longer be accurate for the very low values of Q to be expected in the Earth-ionosphere cavity, but should serve to indicate that the actual peak frequency of the fundamental mode may be considerably lower than 10.6 c./s.

It may be assumed that the cavity is continually being excited by lightning strokes all over the world. To the extent that radio noise at these frequencies is a result of such excitation, the power spectrum of the noise should show peaks with frequencies and values of Q corresponding to the various resonant modes.

* Operated with support from the U.S. Army, Navy and Air Force.

There has been some indication that variations in the vertical electric field below about 20 c./s. are largely local in origin⁵ (for example, moving clouds, pollution of air by combustion products), which would further inhibit the observation of cavity effects.

An earlier attempt⁶ to observe cavity effects of modes of higher order with frequencies greater than 60 c./s. produced some suggestive results, but they were not statistically significant. It was therefore decided, despite the problems just mentioned, to attempt to observe the cavity effects on the spectrum of radio noise at and just above the fundamental frequency.

As in the previous attempt⁶, it was planned to produce the final results by simulated spectrum analysis on a digital computer. For this and other reasons, it was decided to record the raw data digitally in such a format that the original tape recorded at the field site could be read directly into the Lincoln Laboratory IBM 709 computer for processing.

The equipment used to record the radio noise was assembled at a field site in Ipswich, Mass. A block diagram is shown in Fig. 1. The (receiving) antenna was a 120-ft. metal tower which, of course, responded to variations in the vertical electric field. The signal was passed through a low-pass filter which cut off at about 75 kc./s. to prevent strong radio-frequency fields from overloading succeeding stages. A cathode follower was then used to reproduce the signal at a lower impedance-level. This was followed by an audio filter which cut off at about 35 c./s. and was designed to have a minimum at 60 c./s. to minimize interference by power lines (none was ever observed following this filter). The filtered signal was then fed into an audio amplifier. All this equipment was powered by batteries and was located directly at the base of the antenna. The frequency response of the system, measured by replacing the antenna with a signal generator of like impedance, is shown in Fig. 2.

The signal was conducted into the building which contained the recording equipment through an insulated shielded cable. In order to eliminate ground return currents which would result from the small potential difference between the ground at the antenna and the ground at the building, an amplifier with unity

Fig. 1. Recording equipment

Fig. 2. Frequency response of recording equipment

gain was used to sense this potential difference and maintain the recording equipment ground at the potential of the antenna ground. Finally, the signal was sampled 80 times per sec. and the voltage was then converted to a six-bit number, that is, one of 64 levels, and recorded on IBM magnetic tape. Since the highest effective frequency in the signal was less than 45 c/s., no information is lost in the sampling process except for the small quantization error.

The day which was chosen for making these observations, June 27-28, 1960, appeared to be most favourable for minimizing undesired effects. The sky was absolutely clear, the humidity was low (for New England), and the air was fairly calm (straight, sharp jet-vapour trails indicated that this was also true at higher levels). Atmospheric interference in the high-frequency band seemed quite low for the summer-time.

Recordings of the extremely low-frequency radio noise of duration slightly longer than 12 min. were taken on an average once every 2 hr. around the clock for the day indicated. Also recorded for test purposes were sine waves of various frequencies in the pass-band, produced by an oscillator which was substituted on those occasions for the antenna.

During parts of the recording periods the analog signal that was presented to the digital apparatus was also recorded on paper tape, and it was always monitored

on an oscilloscope. A typical sample of the recorded noise is given in Fig. 3. The only exceptions to this apparently random wave-form were large impulses (which corresponded to nearby lightning disturbances heard on high-frequency) which saturated the pen recorder and the digital recorder for periods of up to a second. These increased in frequency of occurrence and intensity during the night and diminished again the next day, although not quite to the level of the previous day. Apart from these bursts, no wave-forms different in character from that shown in Fig. 3 were ever seen. (This contrasts with findings of Schumann and König^{7,8}, who have reported observing signals of sinusoidal character with frequencies near 8 or 9 c/s. on similar paper recordings. Some differences in the shape of their pass-band (principally due to a notch filter they used to eliminate 16½ c/s. interference) may help explain the disparity in observed wave-forms.)

The filtered radio noise signal was compared on an oscilloscope with a calibrated 10 c/s. oscillator, and the root mean square noise voltage was estimated to be about 20 mV.

A programme was written for the IBM 709 computer (largely adapted from the one written for the earlier attempt⁹), which read in a 12-min. block of noise signal from the original tape and, in effect, passed it through a 1 c/s. filter, then squared and integrated the output to give the power in that 1 c/s. band. This was done for all integral frequencies between 5 and 34 c/s. and the results were multiplied by a correction factor to compensate for the system response of Fig. 2.

In mathematical terms, the computer simulated a narrow-band filter the impulse response of which is given by:

$$h(f,t) = \sin \omega t \quad 0 < t < 1 \quad (3)$$

$$= 0 \quad \text{elsewhere}$$

where $\omega = 2\pi f$ and f is an integral frequency between 5 and 34 c/s. The frequency response of this filter is given by:

$$|H(f')|^2 = \frac{\sin^2 \pi(f' - f)}{\pi^2(f' - f)^2} \quad (4)$$

and is shown in Fig. 4 as the solid curve. The peak at the centre would be at the frequency f , and the nulls occur at all other integral frequencies. If we

Fig. 3. Sample of recorded extremely low-frequency radio noise

Fig. 4. Theoretical frequency response (solid curve) of 1 c/s. filter used in processing. Points are results of processing a sine wave of about 10.2 c/s.

call the input signal $x(t)$, then the output of this filter is :

$$y(f, t) = \int_{t-1}^t x(\tau) \sin \omega(t - \tau) d\tau \quad (5)$$

$$= \left(\int_{t-1}^t x(\tau) \cos \omega \tau d\tau \right) \sin \omega t - \left(\int_{t-1}^t x(\tau) \sin \omega \tau d\tau \right) \cos \omega t$$

The power in this band is then estimated from :

$$P(f) = \int_0^T y^2(f, t) dt \quad (6)$$

where $T = 720$ sec. The computer performs all of the operations indicated on the input tape, substituting sums over the sample points for integrals.

The integration process just outlined reduces the fluctuations in the estimate of power $P(f)$, which is a random variable derived from the sample function $x(t)$, so that smaller differences in mean power may be discerned. By a calculation analogous to that presented in ref. 6, it can be shown that the standard deviation $\sigma(P)$ is given by :

$$\frac{\sigma(P)}{E(P)} = \frac{2}{\sqrt{3TW}} \quad (7)$$

where $E(P)$ (the quantity we seek) is the mean value of P , W is the 1 c/s. band-width of the filter, and T is the integration time of 720 sec. (This equation was erroneously given as being smaller by a factor $\sqrt{2}$ in ref. 6.) It can therefore be expected that random fluctuations slightly larger than 4 per cent of the mean power (± 0.18 db.) will appear in the computed spectra, and considerably larger deviations may be accepted as significant spectral structure.

In order to test the system, a sine-wave signal of about 10.2 c/s. was recorded and processed. The results are the points shown in Fig. 4. (More accurately, each point is the result of centring the filter on the frequency indicated below it and finding the response at 10.2 c/s. Due, however, to the symmetry between f and f' in equation (4), the points should all lie on the response curve centred at 10.2 c/s.) It can be seen that the system operates as expected. A further result of these tests indicates that the recorded radio noise is nearly 30 db. above the system noise, so that the latter should not be a consideration in the results.

Ten records of noise were obtained which could be properly processed. Two representative spectra resulting from this processing are shown in Fig. 5. The power, as stated earlier, is computed only at

integral frequencies. These points are joined by straight-line segments for ease in reading them, not to suggest the actual shape of the spectrum.) The records were taken around 4.20 p.m. E.S.T. and 3.50 a.m. E.S.T. The mode structure of these spectra is immediately obvious (as it is on all the remaining records processed), with the power differences being much larger than the predicted statistical fluctuations. The only systematic difference that could be observed among the records is the behaviour below the lowest mode frequency. As already observed, the night-time records were characterized by more frequent and stronger lightning bursts. These would saturate the recorder for periods of a fraction of a second to a second, and would naturally appear as strong enhancements of the spectrum in the region of a few cycles. The very large enhancement observed in Fig. 5 (broken line) at 5 c/s. (and undoubtedly down to about 1 c/s.) is representative of the regular increase and subsequent decrease in close correspondence to the previously noted lightning activity.

Fig. 6 is a composite of all ten processed records. It therefore represents two hours of integration, although the individual 12-min. periods are taken from all parts of the day rather than continuously. The random fluctuations are smoothed out even further, and in this case the points are joined by a smooth curve that is an attempt to suggest the probable shape of the spectrum. No attempt is made to follow the points below the dominant mode where the behaviour is systematically variable, as discussed in the preceding paragraph, and where the sum therefore does not constitute further smoothing.

The resultant spectrum is smooth enough to be read to ± 0.1 c/s. on the original curve, and the peak frequencies were determined for each of the five modes in the range. These are listed in Table 1. Estimates can also be made of the Q of the cavity for each of the modes. The fundamental mode has $Q = 4$, and the value increases regularly (although it is difficult to obtain accurate estimates) until for the fifth mode, $Q \approx 6$.

Fig. 5. Typical spectra of recorded noise (scale of P is linear). Full line, day-time record; broken line, night-time record.

Fig. 6. Composite spectrum of ten 12-min. records of extremely low-frequency noise (scale of P is linear).

Table 1

n	f_n (c./s.)	$\sqrt{\left\{\frac{2}{n(n+1)}\right\}} \times f_n$ (c./s.)
1	7.8	7.8
2	14.1	8.14
3	20.3	8.29
4	26.4	8.35
5	32.5	8.39

Note added in proof. The frequency 7.8 c./s. for the first peak was actually obtained from a more detailed examination of the results, carried out after the submission of this article, in which the simulated filters had a bandwidth of 1/3 c./s. and were separated in frequency by that amount. The points in Fig. 6 are insufficient to determine the first peak to within 0.1 c./s., and an earlier estimate of 8.0 c./s. was obtained from some of the individual records relatively free of corrupting impulse noise at the lower frequencies.

Except for the low value of f_1 , the results seem to be quite consistent with the predicted behaviour. The frequency progression is about what is expected

from equation (1). The quantity $\sqrt{\left\{\frac{2}{n(n+1)}\right\}} \times f_n$,

which from (1) should be f_1 , is also given in Table 1. As can be seen, these values are close to the fundamental frequency but tend systematically to increase with n . This is just the behaviour to be expected, since Q is also increasing with n and the values f_n are therefore decreased proportionately less at the higher frequencies.

It is of interest to recall a marginal observation made in the earlier work⁵ but rejected because of insufficient supporting evidence. There seemed to be some indication there of modes at frequencies of about 63, 69, 75, 81 and 87 c./s. with $Q \approx 10$. These

values extrapolated back to a fundamental frequency of about 8.5 c./s. In the light of the present (stronger) evidence, it seems quite probable that the earlier result did in fact constitute an observation of the continuation of the series of modes reported here.

An incidental result may be noted in connexion with the remarks on the nature of radio noise below 20 c./s. From the depth of the valley below the lowest mode on some of the records, for example, Fig. 5 (full line), it seems likely that, at least under the conditions of these measurements, the noise due to local charge fluctuations in the air does not become dominant until below 5 c./s.

In conclusion, it should be mentioned that while these observations seem to confirm the stable, round-the-clock structure of the Earth-ionosphere cavity modes, they were, after all, made all in one day at one place. Since the properties of the modes (peak frequency and Q) depend on the nature of the lower ionosphere, it is easily conceivable that there are effects that were missed in these observations. There is certainly room for further work, both experimental and theoretical, to obtain a better understanding of this phenomenon.

We thank J. V. Harrington and W. B. Davenport, jun., for suggesting this problem. We are also grateful to R. Cherry, who carried out the machine computations, to R. E. Gay, who implemented the analogue-to-digital conversion equipment, and to J. W. Craig, who designed the audio filter.

THEORETICAL LIMITING THICKNESSES FOR SINGLE SCATTERING IN ELECTRON MICROSCOPY

By DR. N. R. SILVESTER and DR. R. E. BURGE

Wheatstone Physics Laboratory, University of London, King's College, Strand, W.C.2

THE quantitative aspects of electron microscopy have been examined recently by a number of authors¹⁻⁷ and it is generally agreed that accurate measurements of mass-thickness, that is, the product of thickness and density of the specimen, can be made only on specimens for which the contrast in the electron-microscope image is proportional to the mass-thickness (w). (Contrast is here defined as $\ln(I_0/I)$, where I_0 and I are respectively the intensities of the electron beam incident on the specimen and that received at the image plane.) The maximum limit (w_{lim}) of the range within which $\ln(I_0/I)$ is proportional to w is therefore of importance, since its value for given operating conditions of the electron microscope governs the choice of specimens suitable for quantitative work.

Values of w_{lim} have been deduced on theoretical grounds, based essentially on the point of transition from single to multiple electron scattering as the mass-thickness of a specimen increases. Experimental

results^{1,8-11} produced by measurements on the variation of image-contrast with w show that for a variety of operating conditions values of $\ln(I_0/I)$ up to 3 and values of w in the range 0-100 $\mu\text{gm. cm.}^{-1}$ are within the range where the contrast is directly proportional to the mass-thickness of the specimen.

Theoretically the situation is rather confused. At the present time, two theories of electron scattering are in current use, due to Leisegang¹² and Lenz¹³ respectively. Leisegang's theory is restricted to a consideration of elastic scattering only, while Lenz treats both elastic and inelastic processes. The two elastic scattering theories are fundamentally the same, since they are based on the same quantum-mechanical treatment (for example, Bohm¹⁴). Using these two theories of scattering, essentially three different theoretical definitions of w_{lim} have been proposed, giving values of the limiting thickness which differ considerably from one another both in magnitude and in physical implication.

It is the purpose of this article to point out the discrepancy in magnitude between the experimental results and the theoretical estimates of w_{lim} , to review the definitions of w_{lim} and to discuss which of them is physically the most satisfactory, to correct errors which have arisen in the literature in the calculation of some of the theoretical values, and to suggest a system of symbols for the theoretical parameters, since there is no accepted notation in this field of study.

The relation between contrast and mass-thickness under single-scattering conditions is simply expressed by the equation:

$$\ln(I_0/I) = Sw \quad (1)$$

where S is the effective scattering cross-section per gram of the material. For scattering by a single (amorphous) element, S is related to the corresponding atomic cross-section, σ , by the equation:

$$S = \frac{\sigma N_0}{A} \quad (2)$$

where N_0 is Avogadro's number and A is the atomic weight of the material. The theoretical value of w_{lim} , above which S in equation (1) is no longer independent of w , is given by the value of w beyond which the theoretical basis of equation (2) (that is, single-scattering conditions) is no longer valid.

In this article elastic scattering cross-sections will be denoted by the subscript E or e , inelastic by I or i and the sum of the two by T or t . Capital letters indicate the results of integrating the differential cross-sections over all possible scattering angles ($0 \leq \theta \leq \pi$), and small letters indicate integration from a lower limit of the objective-aperture semi-angle, α .

For example:

$$\sigma_T = \sigma_E + \sigma_I \quad (3)$$

$$\sigma_e = \int_{\alpha}^{\pi} \frac{d\sigma_E}{d\Omega} 2\pi \sin\theta d\theta \quad (4)$$

$$\sigma_I = \int_0^{\alpha} \frac{d\sigma_I}{d\Omega} 2\pi \sin\theta d\theta \quad (5)$$

$$S_t = S_e + S_i \quad (6)$$

The values of w_{lim} , based on the definitions given by various authors and evaluated for carbon and an accelerating potential of 50 kV, on the basis of either the Leisegang or Lenz theory are given in Table 1. The definitions are considered separately below.

The first three values of w_{lim} in Table 1 are based essentially on the same definition of the *Aufhellungsdicke* or 'transparency thickness' due to von Borries¹² and represent (apart from the factor 0.53 in the third value) the values of w in which the mean number of elastic scattering acts per electron is unity (that is, for material of unit density the mean free path for acts of elastic scattering). The factor 0.53 has recently been introduced by Zeitler and Bahr³ to produce a value of w_{lim} within which not more than 10 per cent of the incident electrons are scattered elastically more than once. The values of w_{lim} in Table 1 obviously differ considerably according to the definition adopted, and show only an order-of-magnitude agreement with the experimental values already quoted.

The von Borries definition can only be valid when elastic scattering is much more important than inelastic and predicts a value of w_{lim} , which is independent of the objective aperture. Since the elastic-scattering theories predict that $S_E \approx S_e$ for the usual apertures in electron microscopy ($10^{-3} \leq \alpha \leq 10^{-2}$ radian), the dependence on aperture can be neglected on this definition. Lenz's theory, which deals with inelastic as well as elastic scattering, predicts that for high Z , $S_e \gg S_i$, but that for low Z , for example, organic specimens, $S_e \approx S_i$. This means that, in general, the restriction of a definition of w_{lim} to the value of $1/S_E$ cannot be maintained. However, it is important to examine the values of $1/S_E$ given on the basis of the Leisegang and Lenz theories in order to explain the apparent discrepancy between the values. The discrepancy is at first sight disturbing, since both theories have a common basis in quantum mechanics.

The difference between the values of $1/S_E$ arises partly from a different choice of approximation to the electronic charge distribution of the scattering atom. The value of σ_E is proportional to the mean squared radius of the distribution, denoted by θ/Z (ref. 13) or $6R^2$ (ref. 12). Lenz, using Hartree wave functions, gives $\theta = 9.10 (a_H)^2 Z^{1/3}$ for carbon, whereas Leisegang uses the expression $R = a_H Z^{-1/3}$ (that is, $\theta = 6 (a_H)^2 Z^{1/3}$). The values of θ thus differ by a factor of 1.52, while the remaining discrepancy can be accounted for as follows.

Differential scattering cross-sections are often expressed in terms of a characteristic scattering angle, χ_0 (refs. 17, 12) or θ_0 (refs. 13, 2, 6), and σ_E is proportional to $\frac{1}{\chi_0^2}$. If λ is the wave-length of the scattered electron, then:

$$\chi_0 = \lambda/2\pi R \quad (7)$$

which reduces, using the Leisegang approximation for R , to:

$$\chi_0 = Z^{1/3} \frac{e^2}{c\hbar} \frac{\sqrt{1-\beta^2}}{\beta} \quad (8)$$

where β is the ratio of the velocity of the electron to the speed of light. The expression which appears in Leisegang's paper¹² is:

$$\chi_0 = 0.48 Z^{1/3} \sqrt{1-\beta^2}/\beta \text{ (degrees)} \quad (9)$$

whereas on re-calculation we find that the numerical constant has the value 0.418. Leisegang (personal communication) agrees with us, and finds he had carried over a numerical error from the earlier paper of Molière¹⁷. The result is that theoretical cross-sections calculated on the basis of equation (8) (see, for example, Bahr¹, Zeitler and Bahr³, De and Sadhukhan¹⁸) are about 30 per cent too small. Combined with the factor 1.52 mentioned above, this explains the difference between values of S_E derived from Leisegang's paper¹² and those derived from Lenz's work¹³.

Another error has been the occasion of differences between Lenz's published values and those calculated by others (refs. 3, 19, 5, 20) from his expressions. In his equation for σ_E , there appears the term θ/a_H , where $a_H = \hbar^2/me^2$ is subject to relativistic variation through the mass, m , of the incident electron. The value of θ is also expressed in terms of a_H , but in this case a_H is merely a convenient length (the Bohr radius of the hydrogen atom) and is invariant. By cancelling out a_H in the Lenz expres-

sion, one thus loses a factor (> 1) which becomes increasingly important at higher accelerating voltages. Leisegang's theory has not been liable to this error, because the relativistic variations always appear explicitly in the equations.

The two possibilities of including both elastic and inelastic scattering in a definition of the limiting value of w for single scattering, namely, $1/S_T$ and $1/S_i$, have both been used^{16,3}. While $1/S_T$ is a logical and rigorous extension of von Borries's definition for elastic scattering and gives a valid limit for the accurate measurement of differential cross-sections (the subject of Haine and Agar's paper), it can bear little relation to the effect of scattering on the image-contrast, since most electrons, if inelastically scattered, still reach the image plane under normal conditions. This raises the question whether, in considering the effect of plural scattering, deflexions through all angles should be given equal weight; an electron which is inelastically scattered through an angle much smaller than α and is then scattered through (probably) a larger angle is effectively singly scattered so far as the image contrast is concerned.

The above kind of argument explains why inelastic scattering is ignored in defining a critical thickness for conditions in which $S_i \ll S_e$, although inelastic scattering, and multiple scattering in the rigorous sense, are still undoubtedly taking place. If this procedure (that is, the neglect of scattering processes with deflexions smaller than α) can be justified, a similar case must exist for neglecting the total inelastic cross-section (calculated for $\alpha \rightarrow 0$) when finite apertures are used. Thus when inelastic scattering has to be taken into account, a reasonable course would be to use S_i in estimating its effect, and to use $1/S_i$, rather than $1/S_T$, as a measure of critical thickness. This course appears to have been followed by Coslett³, since he mentions a critical mass-thickness, x_c , given by $x_c = 1/\mu$, where μ corresponds to our S_i . The value of $1/S_i$ is the theoretical mass-thickness, in which the mean number of scattering acts per electron with a deflexion greater than α is unity.

Table 1. DEFINITIONS AND VALUES OF THEORETICAL LIMITING THICKNESSES FOR U AT 50 kV.

Author	Definition w_{lim}	Scattering theory	w_{lim} ($\mu\text{gm.cm.}^{-2}$)
von Borries (ref. 15)	$1/S_E$	Leisegang	21.7
von Borries (ref. 16)	$1/S_E$	Lenz	11.2
Zeitler and Bahr (ref. 2)	$0.53/S_E$	Leisegang	11.6
Haine and Agar (ref. 16)	$1/S_T$	Lenz	1.8
Coslett (ref. 3)	$1/S_i$	Lenz*	8.3

* Using values of $R = 0.529 Z^{-1/2} \text{ \AA}$, $\alpha = 5 \times 10^{-3}$ radian

It appears to us that the logical theoretical definition of the critical thickness for single-scattering in electron microscopy is $1/S_i$, which takes both elastic and inelastic scattering into account, converts into the von Borries definition at high Z or large-aperture angles where $S_i \simeq S_e \simeq S_E$, and includes the effect of variation of aperture on the number of electrons which reach the final image plane.

We thank Prof. J. T. Randall for advice and discussion.

PROTEIN CATABOLISM

By DR. HARRY WALTER

Radioisotope Service, Veterans Administration Hospital, Brooklyn, New York

SIGNIFICANT progress has been made in recent years in determining the mechanism involved in protein biosynthesis¹⁻³. This process has been shown to depend on the enzymatic formation of activated amino-acids (as amino-acyl adenylates) and on their transfer to soluble ribonucleic acids. A highly efficient (although incompletely understood) incorporation of these amino-acids bound to soluble ribonucleic acids into protein in the microsomes then takes place. On the other hand, relatively little attention has been given to protein catabolism. It is still not established whether protein catabolism involves a reversal of the steps known to occur in protein biosynthesis or proceeds by an entirely different mechanism. It is the purpose of this article to show how the results of several investigations bearing on protein catabolism in higher organisms which have been variously interpreted actually support the thesis that an amino-

acid derivative is an intermediate degradation product of protein. Such a mechanism not only explains the experimental data cited but is also particularly attractive because of its energy-conserving nature, and because, as mentioned above, amino-acid derivatives have been demonstrated as intermediates in protein biosynthesis⁴.

The experimental results of Whipple and co-workers⁵ were interpreted by postulating an intermediate in the breakdown of one protein and the biosynthesis of another. These investigations showed that when serum proteins containing carbon-14 lysine were injected intravenously into dogs, 30-40 per cent of the radioactivity, still in the form of lysine, was incorporated into the tissue and organ proteins without appreciable loss of activity as carbon-14 dioxide in the expired air. When similarly labelled proteins were fed to dogs, a high content of

carbon-14 dioxide was expired. Whipple concluded that the mechanism of transfer of carbon-14 from labelled plasma protein to organ protein did not involve breakdown to free amino-acids, but rather proceeded by protein cleavage only to the polypeptide stage. The organ proteins were formed by the subsequent re-assembly of these peptides.

In pursuing the problem of the mechanism involved in the transfer of labelled amino-acids from one protein to another, Francis and Winnick⁶ and Friedberg and Walter⁷ attempted to inhibit the transfer of amino-acids from one protein to another by flooding the system under study with large amounts of unlabelled amino-acids. It was found that the formation of newly labelled protein from labelled administered protein could not be decreased or inhibited by this method. Loftfield and Harris⁸ have interpreted the above results^{6,7} on the basis that exogenous (injected or fed) and endogenous (derived from protein degradation) amino-acids do not readily reach equilibration. The formation of intermediates other than free amino-acids in the breakdown of one protein and the synthesis of another would, however, be in harmony with the observations^{6,7} and with the interpretation of Loftfield and Harris already mentioned. Such degradation products, far from readily reaching equilibration with free amino-acids, would also be preferred precursors in the synthesis of new protein. It is of interest to note in this connexion that it has been demonstrated that a considerable part of newly synthesized protein is derived from the breakdown products of endogenous protein⁸.

More direct experimental evidence for intermediates in protein degradation comes from the work of Simpson⁹ and from that of Steinberg and Vaughan¹⁰. They demonstrated that the release of radioactivity from labelled proteins in rat liver slices was depressed by anaerobic conditions, by cyanide, by 2,4-dinitrophenol, and by certain amino-acid analogues. This work implies that protein catabolism is tied to a supply of energy. It has been suggested¹⁰ that a linkage between protein catabolism and protein biosynthesis might also be involved. Korner and Tarver¹¹ investigated, under cell-free conditions, protein catabolism in the sub-cellular fractions of labelled rat liver and found that release of amino-acid from nuclei and mitochondria is inhibited by anaerobiosis and by uncoupling oxidative phosphorylation. More recently, Penn¹² reported that the degradation of serum albumin by rat liver mitochondria is also dependent on an energy supply and that some amino-acid derivatives, detectable by spectrophotometry, appear to be involved as intermediates. Although these experiments cannot be unequivocally interpreted at present (see Korner and Tarver¹¹), the results of Simpson, Steinberg and Vaughan and Penn certainly suggest that protein degradation is not simple proteolysis, and that intermediates are involved in protein catabolism.

There is further evidence which indicates that intermediates other than free amino-acids might be involved in protein degradation. When radioactively labelled proteins, peptides, and amino-acids were injected into yolks of embryonated chicken eggs¹³, the rate and extent of uptake of label into the chick embryonic protein were found to be identical for the three types of precursors. Considering that there are no free amino-acids in the yolk, but large amounts of diluting protein, it was concluded that protein is the preferred embryonic protein precursor. The uptake of homologous and heterologous proteins

by the embryo was identical. Furthermore, the site of protein breakdown appears to be in the yolk, whereas protein synthesis occurs in the embryo proper. Since there is no equilibration between added free amino-acids and those derived from yolk protein, I was led to the conclusion that an intermediate, other than free amino-acids but one directly derivable from protein, is involved.

Chin, Tannenbergs and Moldave¹⁴, in experiments with Ehrlich ascites cells, recently found that incubation with isotopic free amino-acids led to the accumulation of considerable amounts of free amino-acids within the cell during incorporation into proteins. Incubations with isotopic proteins led to labelling of proteins without significant accumulation of intracellular free amino-acids. These results are interpreted by Moldave as indicating intermediates other than free amino-acids in the degradation of one protein and the subsequent synthesis of another.

Conceivable intermediates in the process of protein breakdown and new protein synthesis are: free amino-acids, peptides and amino-acid derivatives (that is, some forms of activated amino-acids). I have shown that the experimental evidence cited points to intermediates other than free amino-acids. Of the two remaining possibilities, the amino-acid derivative is the more probable choice, since a large number of experiments conducted in the past ten years have made peptide intermediates in protein metabolism most unlikely. Walter *et al.*¹⁵ found that amino-acids and peptides derived from homologous serum proteins were incorporated into serum proteins (as well as organ proteins) at essentially the same rate and to the same extent. This cast doubt on the role of peptides derived from proteins as intermediates in protein synthesis. Other experiments¹⁶⁻¹⁷ dealing with the breakdown of serum proteins, transfused from donor to recipient at various times after injection of labelled amino-acids, also have led to the conclusion that peptides are not involved. Such residues of individual amino-acids incorporated into serum proteins at different times are lost from these proteins at the same rate.

In a series of *in vivo* experiments, Simpson and Velick¹⁸, Askonas *et al.*¹⁹ and Muir *et al.*²¹ investigated the problem of protein synthesis by administering labelled amino-acids to animals and determining the specific radioactivities of these amino-acids in various parts of the peptide chain of isolated, specific proteins. They found identical specific radioactivities in the injected amino-acids derived from different parts of a protein. This indicates that the entire protein molecule was formed at the same time and from the same amino-acid pool. In this connexion an apparent contradiction to the argument must be mentioned. Anfinsen and co-workers^{22,23}, in their investigations *in vitro*, found differing specific activities of incorporated labelled amino-acids derived from various parts of ovalbumin, insulin and ribonuclease. These authors concluded that peptides were intermediates in protein synthesis. However, Loftfield and Harris⁸ showed, in subsequent experiments, in which rats were continuously infused with labelled valine, isoleucine and leucine, that the specific activities of the intracellular free valine, isoleucine and leucine of liver and the specific activities of these amino-acids in a protein (ferritin) formed by the liver were identical. It thus appeared that if peptide intermediates are involved, they must be derived only from amino-acids and not from preformed protein. Whether labile amino-acid derivatives are the intermediates involved in

protein breakdown and synthesis of new protein could not be experimentally decided by these investigations. Such amino-acid derivatives could also give rise to free amino-acids during the isolation of 'free' amino-acids from tissue.

I have shown how a variety of experimental results dealing with aspects of protein catabolism can all be interpreted uniformly by postulating amino-acid derivatives as intermediates in the re-utilization of amino-acids derived from one protein for the synthesis of another. In the transfer of labelled residues from one protein to another, the amino-acids did not exchange with large pools of added amino-acids⁵⁻⁷, a fact which suggests the presence of an intermediate. Peptides were excluded as intermediates on the basis of the rate of incorporation of amino-acid into various parts of the same protein¹⁸⁻²¹, and on the basis of identical specific activities of intracellular amino-acids and of these amino-acids in a protein in rats continuously infused with labelled amino-acids⁸.

The experiments of Simpson⁹, Steinberg and Vaughan¹⁰ and Penn¹¹ have shown that protein degradation is not simple proteolysis. Specific energy requirements for protein catabolism were indicated. Intermediates were shown to be involved in protein degradation, and it has been suggested that these might be similar to some of the intermediates known to participate in protein biosynthesis^{10,12}.

The preferred utilization of precursor protein (rather than peptides or amino-acids) in a system¹³ in which protein breakdown and protein synthesis are apparently spatially removed led to the conclusion that an amino-acid derivative, not in equilibrium with added free amino-acids, is involved as an intermediate. In other experiments it was shown⁸ that the breakdown products of endogenous protein are highly efficient precursors of newly formed protein. Furthermore, the demonstration¹⁴ at a time of active protein synthesis of the accumulation of labelled free amino-acids in certain cells when labelled free amino-acids are supplied but not when labelled protein is supplied is again indicative of the participation of amino-acid derivatives as intermediates.

The possible analogy between the cleavage of peptide bonds and the enzymatic cleavage of other macromolecules has been pointed out¹⁵. For example, in the cases of glycogen and ribonucleic acid, which

also can be split hydrolytically, the enzymatic cleavage need not be hydrolytic^{16,17}. The cleavage of peptide bonds may similarly require an acceptor substance. Amino-acid derivatives have been shown to be intermediates in protein synthesis. The re-utilization of amino-acids from one protein for the synthesis of another involving amino-acid derivatives as intermediates would therefore conserve energy. A large number of the experiments cited have implicated an intermediate other than free amino-acids in the breakdown of proteins. Since peptides have been excluded by a number of investigations as the intermediates involved, the most likely intermediate is an amino-acid derivative. It is possible that this amino-acid derivative is similar to, or identical with, one of the intermediates known to participate in the anabolic process.

FORMS OF TOBACCO MOSAIC VIRUS

By PROF. J. G. BALD

College of Agriculture, University of California, Los Angeles

THE study of strains or variants of tobacco mosaic virus may be simplified by considering the natural association between host species and the forms of the virus infecting them in the field. The forms of the virus occurring naturally in different host species have distinctive biological properties which divide them into categories similar to those delimited by biophysical properties. Data on the constitution of the tobacco mosaic virus proteins show similarities and differences between strains that appear congruent with the same grouping. Forms of virus may be distinguished partly by

physical and chemical properties, partly by biological criteria.

Siegel and Wildman¹ and Ginoza and Atkinson² studied differences in biophysical properties among 8 tobacco mosaic virus strains. Four of the 8 were single-lesion selections characteristic of virus populations in 3 host species. They were U1 and U2, representing majority and minority components in a sample of tobacco mosaic virus^{3,4}; U5, from *Nicotiana glauca* Grah.⁵; and U8, Holmes's strain from the ribwort plantain, *Plantago lanceolata* L.⁶. These 4 strains were placed according to biophysical differen-

oes in 3 groups. Two strains, *U2* and *U5*, were placed in the same group. Though they were from different hosts and gave different mosaic symptoms, they had similar biophysical properties. Included in the *U1* group were 2 mutants from *U1* type isolates, one, *U4*, the heat-induced masked strain⁷, the second, *U7* from ultra-violet irradiated *U1* virus. Also in the group was *U3*, possibly a derivative or minor component of the ribgrass isolate. A fourth group was reserved for *U6*, a yellow mutant of *U1* with changed biophysical properties.

Knight *et al.*⁸⁻¹⁰ found the amino-acid content in the protein fraction of an ordinary severe tobacco mosaic virus isolate, like *U1*, similar to that of the masked strain, *U4*. There were differences in the amino-acids of this pair, the ribgrass strain (*U8*) and a yellow mutant similar to *U6*. The chemical and biophysical data agree in distinguishing some strains and grouping others. In a general sense, these data bear out the expectation that similarities or differences in the constitution of the protein shells of virus strains should be reflected as similarities or differences in biophysical properties.

The main biological criterion for a form may be defined by the presence and persistence, as a natural infection in one or more host species, of a type of tobacco mosaic virus with uniform biophysical properties. A form need not, and in practice does not, consist of one symptom variant. It is subject to mutation and selection that may change the level of systemic symptom expression in whole populations¹¹. The masked strain is an example showing that the constitution and properties of the virus protein shell may remain unaffected by such changes⁸. Commonly also mutation may produce variants of the virus, like *U6*, with properties beyond the limits of the original form, but these are soon eliminated in the field by competition with better adapted strains. They fail to pass the test of persistence under natural conditions. It is possible that a strain like *U6* might infect a new host in which it could persist, or changes like that reported for the cowpea strain of the virus¹² might occur in Nature. Such events would be evidence for the production of new forms by mutation, but they would not eliminate the essential discontinuity between forms.

The dominant tobacco form of the virus, corresponding to strain-group 1 of Siegel and Wildman¹, has special biological effects marking it off from other forms of tobacco mosaic virus. It causes systemic symptoms in some *Nicotiana* spp., including *N. sylvestris*, which react to many tobacco mosaic virus isolates with necrotic local lesions. These host reactions are heritable^{13,14}. The dominant tobacco form also produces characteristic yellow mutants in systemically infected host plants¹⁵. Cytologically, it causes typical reactions in invaded cells (unpublished). Such biological characters, as well as biophysical and chemical data, may be used to distinguish between the tobacco form and others.

Johnson and Valleau¹⁶ tested many samples of tobacco mosaic virus, some from stored tobacco leaf up to 50 years old, some collected directly from field crops. They kindly sent a portion of their collection of isolates for further testing in this laboratory. The majority of symptom variants were similar to *U1* in their reactions, but among them were mild isolates similar to *U2*. The forms of virus most common in tobacco seem to have remained almost the same for 50-80 years.

In southern California, isolates of tobacco mosaic virus from naturally infected *Nicotiana glauca* have produced necrotic local lesions on *N. sylvestris*⁵, though single lesion isolates varied greatly in symptom expression. A detailed study of one variant, *U5*, has shown its biophysical properties to be almost indistinguishable from those of *U2*¹⁷. Variants giving host reactions similar to those of *U5* have been found in *N. glauca* elsewhere^{17,18}.

U5 was isolated from *N. glauca* in disturbed natural vegetation on the campus of the University of California at Los Angeles. Another species in the same plant community, *Solanum xanthii* Gray, was also found infected with tobacco mosaic virus. The dominant form in *S. xanthii* gave small white local lesions on first transfer to *N. glutinosa*, instead of the characteristic necrotic local lesions of *U1* and *U2*; and on *N. sylvestris* it produced mosaic symptoms. It was thus distinguished from both the *U1* and *U2* forms of tobacco mosaic virus. The *S. xanthii* virus included 2 minor components: one appeared to be of the *U1* form, the other caused necrotic local lesions even in Turkish tobacco, variety Samsun. Two species of Solanaceae, *N. glauca* and *S. xanthii*, growing in the same plant community for a number of years, were infected with different forms of the virus.

There is evidence from southern California¹⁸ and numerous references in the literature¹⁹⁻²² that tomato normally carries a form of tobacco mosaic virus differing from that in tobacco. It includes many symptom variants giving necrotic local lesions on *N. sylvestris*. Still other forms of the virus appear regularly in host species from families unrelated to Solanaceae^{8,12,23}. Though some of these forms of the virus are insufficiently differentiated, the general pattern is becoming clear. Natural infections in a single plant species seem to consist mainly of one or a small number of forms. Generally one form of the virus is dominant. Symptom variants of a form that is dominant in one host species may be present as minor constituents of the virus infecting other species. The occurrence, in widely separated regions, of the same or similar forms of the virus in a particular host, for example, in tobacco, *N. glauca*, or tomato, minimizes the chance that these associations are merely of regional origin.

The mutual acceptance between a host species and a well-adapted form of the virus seems to be associated with the constitution of the virus protein (see above). To assume that a causal relationship exists between the nature of the protein and initial acceptance of the virus particle may be premature, but it accords well with the view that infection is a 2-step process²⁴⁻²⁶. The shedding of the protein shell and release of the nucleic acid depend on the acceptance of a virus particle at an appropriate site in the host tissue. The protein surrounding the core of nucleic acid is more likely to influence the first stage of association with structural elements of the invaded cell than is the nucleic acid itself²⁵. Re-infection and further multiplication of newly formed virus particles, after local or systemic transport to non-infected cells, again demands acceptance at appropriate sites. At each re-infection, if it occurs from whole virus particles, initial acceptance would be influenced by the constitution of the virus protein, and in turn would influence the chances of the nucleic acid being freed to reach appropriate sites for multiplication. The degree of adaptation of the protein shell to the cells of a particular host may thus introduce a correspond-

ing degree of specificity into the initial reactions of a plant species to the form of virus infecting it. In the final act of infection the nucleic acid would presumably be decisive.

At a different level there is evidence on the nature of selectivity between host species and forms of tobacco mosaic virus. First, a process of exclusion may exist. The tobacco varieties responding to a form of virus with necrotic local lesions are essentially immune to it in the field¹⁷. The U1 form alone is likely under natural conditions to infect tobacco varieties reacting with necrotic local lesions to U2. In a more positive sense, variants of the U1 form are adapted to tobacco because they multiply rapidly to high concentrations, and are invasive but not crippling to the host plant. The reason for the dominance of the U2-U5 form in *N. glauca* appears to be of this sort (R. A. Solberg, unpublished). The distribution of U5 in the younger tissues of infected *N. glauca* is somewhat less patchy than that of U1, and the U5 virus approaches closer to the stem apex of infected plants. During a long period under natural conditions of serial transmission this difference should be enough to allow symptom variants of the U5 form to appear as the sole or the dominant type of tobacco mosaic virus in *N. glauca*—as they do.

The persistence in tobacco of low concentrations of U2 mixed with the dominant U1 form indicates that the 2 forms may have slightly different requirements for multiplication or re-infection, giving U2 a competitive advantage at a limited proportion of multi-

plication sites. In general this may explain why minor forms of tobacco mosaic virus are found mixed with dominant forms in a number of host species.

A NEW INTERPRETATION OF *JAMOYTIUS KERWOODI* WHITE

By ALEXANDER RITCHIE

Grant Institute of Geology, University of Edinburgh

JAMOYTIUS KERWOODI White is based on two specimens from the Upper Silurian sediments of Logan Water, near Lesmahagow, Lanarkshire, about half a mile upstream from Logan House. The specimens are B.M.11284 (holotype) and B.M.11285. White¹ described the animal as an agnathan with the following characteristics: "No armour or endoskeletal calcification; notochord persistent; simple lateral fin-folds present; median fin-fold represented by elongated dorsal and anal fins. Eyes probably simple, very large and anteriorly placed. Muscle segments simple and numerous with single flexure and undivided by horizontal septum. Mouth? terminal; intestine short and straight".

The order Euphanerida and family Jamoytiidae were erected on the basis of the above characters. This interpretation placed *Jamoytius* in an important position in relation to early vertebrate evolution, and various authors²⁻⁶ have commented on the original interpretation and on the phylogenetic position of *Jamoytius*.

White regarded *Jamoytius* as a primitive naked fish-like chordate, probably "a conservative element of the main stock from which the various groups of craniate chordates arose". He considered *Jamoytius* as a possible ancestor of the living Acrania, for example, *Amphioxus*. Berrill³ commented on the absence of branchial apparatus and suggested that *Jamoytius* had a pharynx and atrium comparable with that in *Amphioxus*. He also speculated on the

nature of the eye. Stensio⁴ re-interpreted the "carbonized muscle remains" as scale rows and noted the resemblance to the scales of some of the Anaspidae. He assigned the family Jamoytiidae to the super order Anaspidae. Tarlo⁵ confirmed Stensio's conclusions, and re-interpreted other parts of the holotype, for example, dorsal fin rays as ridge scales.

The importance of any new material of this animal is thus obvious, and this work concerns the discovery of two further specimens at the original locality. The first (in counterpart F.R.1393 a and b), collected by Prof. F. H. Stewart, is a large individual, lacking head and tail. The second (A.R.59.103), an almost complete specimen discovered by me, has been prepared to expose the ventral (?) surface (Fig. 1b). Examination of material in the Scottish Geological Survey, collected by Macconochie and Tait, yielded one fragment (in counterpart G.S.E., 11882, 11883), and a poorly preserved specimen was found in the Slimon Collection, Kelvingrove Museum, Glasgow. A small individual bringing the total to seven has also been discovered in material purchased by the Department of Geology, Princeton, from Tait in 1923 (P.U. 12865 in counterpart).

Examination of the new material reveals that the original interpretation must be modified, although the basic concept of body-shape, lateral and median fin-folds appears sound. The new evidence concerns the scales, eyes, mouth, branchial apparatus and caudal fin. The segmental structures in the holotype,

Fig. 1. *Jamoythus kerwoodi* White. a, The holotype, B.M.11284, simplified drawing after White (ref. 1, text Fig. 1) re-interpreted with additions; b, the new complete specimen, A.R. 59.103, with a portion of the body restored from the counterpart. E, eye; M, mouth; B.A., branchial apparatus (or apertures); L.F.F., lateral fin-fold.

Both specimens from the Logan Water, Lanarkshire. ($\times \frac{1}{2}$)

B.M.11284 (ref. 1, text Fig. 1) were interpreted as carbonized remains of body muscles (myomeres) separated by clear infillings representing the vanished septa (myocommata). Evidence against such an interpretation is as follows: of the seven known specimens, six have the segmental structures preserved, and several of the specimens show varying degrees of relief in these structures. The poorly preserved B.M.11285 is thus unrepresentative and misleading. It now seems certain that the preserved structures were originally more substantial than myomeres and myocommata and are remains of exoskeletal ossification or scales, as suggested by Smith⁵ and Stensio⁶. The structures interpreted by White as muscle fibres are a cross-striation ornamentation on the scale surface, or tubercle rows such as are present in the Anaspida. The ridges representing "the vanished septa" may be interpreted as the thickened basal ridges of the scales, running dorso-ventrally, but I feel that the evidence for this is not conclusive.

A.R.59.103 was embedded in a laminated grey siltstone, and extensive preparation was required to expose the complete fossil, which is little more than a carbon film. The surface exposed appears to be the ventral side of the animal. (The holotype, B.M.11284, is probably the dorsal side with some of the ventral structures showing through.) The animal as preserved is 21–22 cm. in length and dorso-ventrally flattened (Fig. 1b). The body axis has been twisted after death through almost 90°. Three well-defined structures in the unarmoured head region are interpreted as lateral eyes and a mouth. The mouth (M) is median sub-terminal and roughly circular (5.0–5.5 mm. in diam.) with a distinct dark rim (1 mm. wide). It thus resembles somewhat the mouth in the living cyclostomes. Very small denticle-like structures were observed on part of the rim. The two stains interpreted as eyes (E) are moderately large (3–4 mm. in diam.), lateral and situated about 1 cm. posterior to the mouth. The structures in the head region of B.M.11284 (ref. 1, text Fig. 1) can be re-interpreted in view of this discovery. The lateral stain (E) interpreted as an eye is indeed such, but the well-defined, oval object in a terminal position (E) is the mouth. The other eye is situated on the blunt protuberance to the right of the mouth, where a dark stain can be seen, both in the specimen and in White's figure, although it is less distinct than the left eye.

The well-developed (and ossified) branchial structures which are so characteristic of the known Anaspida are not present in *Jamoythus*, and their absence has led several authors to suggest the existence of a pharynx and an atrium. One of the most surprising of the new discoveries was that the holotype B.M.11284 does have traces of the branchial apparatus preserved. While examining B.M.11284, using optical equipment of a higher quality than that available at the time of the original description, I was able to distinguish a series of exceedingly faint structures extending backwards from just behind the right eye to a point opposite the eighth preserved scale row. These structures (Fig. 1a, B.A.), apparently seven in number, may be the branchial apertures or even the outline of the gill sacs themselves, in which case the external openings could be quite small, as in the lamprey. The presence of 'advanced' branchial apparatus disproves Berrill's suggestion⁷ of a pharynx and atrium, and settles the argument as to whether *Jamoythus* could have given rise to the modern Acrania.

The scale rows in A.R.59.103 first appear some 4 cm. from the anterior margin of the head and are well preserved along most of the length of the body, but become very faint near the tail. The scales show no indication of having been arranged in rows like those of the Anaspida and seem rather to have been continuous from the mid-dorsal line to the ventral surface, where they fall short of the mid-line, leaving a scale-free ventral strip (1.0–1.5 cm. wide) which extends for most of the length of the body and widens underneath the head.

The structures in B.M.11284 which White (ref. 1, text Fig. 1, L.F.F.) interpreted as the lateral fin-folds tucked underneath the body, and which Westoll⁸ suggested were the remains of the dorsal and anal fins, are interpreted here as the ventral termination of the body scales, mentioned above. It seems more likely that the ragged patches interpreted by White as displaced skin (D.S.) are, in fact, the lateral fin-folds with faint traces of the fin rays preserved. In A.R.59.103 the scales are only occasionally strongly disrupted, a cross-striation ornament is present and the scale surface has been irregularly fractured on a minute scale. The scales almost certainly reflect the underlying myomeres, with single forward flexure which is more acute anteriorly than posteriorly.

Only a faint outline of the caudal region remains; the axis of the tail appears to be twisted and it seems likely that *Jamoythus* possessed a reversed heterocercal (hypocercal) tail such as is found in the Anaspida.

The second of the new specimens (F.R.1393 a and b) lacks both head and tail but shows clearly the scales and other structures of a portion of the body 13 cm. long. The ventral termination of the scale rows is well preserved, and some longitudinal striation is seen in the scale-free strip. Scale relief is strong and the size of the scales indicates that this individual was the largest of the seven specimens.

The fragment with counterpart (G.S.E., 11882, 11883) from the Scottish Geological Survey has the best-preserved section of the lateral fin-fold yet seen. The fin is broad with a well-defined outer margin and at one end shows faint but definite fin rays running almost to the margin. Scale relief is strong. The Princeton specimen (P.U.12865 in counterpart) and that found in the Kelvingrove Museum, Glasgow, are both small individuals and not particularly well preserved.

Several of these specimens possess structures comparable with those which White interpreted in the holotype as notochord and intestine; but more and better preserved material is required before this and other aspects of *Jamoytius* can be satisfactorily explained. In brief, the new evidence concerns the presence of exoskeletal ossification (scales); lateral eyes; a terminal, subcircular mouth; a branchial apparatus not unlike that in the Anaspida and the living cyclostomes; fin rays in the lateral fin-folds; a hypocercal (?) tail. *Jamoytius* is too far advanced to be an ancestor of the living Acrania and shows a close relationship with the Anaspida. Whether it is itself an anaspid¹ is a matter for speculation; but of all the known fossil Agnatha, *Jamoytius* would seem to be the closest to the living Cyclostomata. The age of the enclosing sediments is not yet accurately known, but marine invertebrate faunas from both above and below the *Jamoytius* horizon are indicative of the Wenlockian (or even earlier) rather than the Ludlovian as was previously thought. The "Ludlow fish-bed" of Peach and Horne² from which the specimens come is actually much lower in the succession than the "Ceraticaris Beds" with which they were originally correlated. *Jamoytius* and the two coelolepids found in the same bed are the earliest complete chordates yet found in Britain, and their relatively high degree of organization indicates a

long pre-Wenlockian history. It is hoped that more material will be discovered during my work in the area and the results will be published in detail at a later date.

I wish to thank Dr. E. I. White, British Museum (Natural History), for advice and for the use of facilities to study the original material; Mr. H. A. Toombs; Dr. L. B. Tarlo for advice and the use of a manuscript (in the press); Mr. R. Wilson, H.M. Geological Survey; Prof. F. H. Stewart for the loan of his specimen; Dr. G. Y. Craig, who supervised the work and criticized the manuscript; the Geological Survey, Edinburgh, and Kelvingrove Museum, Glasgow, for the loan of material. The work was carried out under a research grant from the Department of Scientific and Industrial Research.

HOPLOMEMERTINES, MYXINIDS AND DEUTEROSTOME ORIGINS

By DR. DONALD D. JENSEN*

Zoological Laboratory, University of Groningen, The Netherlands

THE metazoa are generally dichotomized into the Protostomia, in which the embryonic blastopore becomes or is associated with the mouth, and the Deuterostomia, in which the embryonic blastopore becomes or is associated with the anus¹. The hoplonemertines (an order of the phylum of proboscis worms, Rhynchocoela or Nemertina)² develop in a way which is not typical of either group, the blastopore being quite separate from both mouth and anus invaginations³, which suggests that this proterostome group might be transitional to the deuterostomes. If this is the case, organ homologies between hoplonemertines and deuterostomes are to be expected and the deuterostome group with which most homologies are shared would be identified as the most primitive of the deuterostomes. A surprising number of homologies, some of which were early suggested by Hubrecht⁴, appear to be shared by the hoplonemertines with the myxinoid cyclostomes⁵, the most primitive vertebrate group.

These homologies are presented in the following two paragraphs. Like-numbered structures are those which resemble each other and are presumed to be homologous.

In myxinoids the *nasopharyngeal duct* (1), *mouth* (2) and *gill slits* (3) develop from a series of lateral expansions of an ectodermal foregut which perforate to form slit-like openings to the exterior⁶. On the dorsal roof of the nasopharyngeal duct is the

glandular hypophysis (4), which is intimately connected in the development of vertebrates with the *anterior somites* (5)⁷ and the notochord. The notochord is composed of a tubular multi-layered fibrous *sheath* (6) surrounding vacuolated gelatinous *notochord contents* (7) in which lies a flat, fibrous band, the *notochord strand* (8), extending along the notochord axis. *Skeletal cartilage* (9) first appears between and comes to surround the hypophysis and the anterior end of the notochord. Cartilage also is found superficially, associated with *horny teeth* (10). Associated with, and just ventral to, the notochord sheath is the *dorsal aorta* (11), a major vessel of the *closed circulatory system* (12). The digestive tract has a prominent ventral *liver* (13) and terminates in a definite *anus* (14). Sense organs include a pair of inverse retina *lateral eyes* (15), a vestige of the direct retina *pineal eye* (16) found in other vertebrates, a pair of *labyrinth organs* (17), *neuromast organs* (18) of taste and the lateral line system, and *olfactory organs* (19). The olfactory organs, which lie in the nasopharyngeal duct, are closely associated with the *dorsal neural tube* (20). Both types of structures develop from the ciliated neural plate, which invaginates as a groove and closes over at the neuropore to form the neural tube and an anterior external lip, the primordium of the olfactory organs. The eyes and olfactory organs are connected directly to the dorsal neural tube, but other sense organs and all muscles are connected to it by *solid nerves* (21) which connect to the dorsal sensory *alar plates* (22) and the ventral motor *basal plates* (23) of the dorsal neural tube.

Fig. 1. Revised deuterostome phylogeny

In *Malocobdella*, a form usually classed separately but closely related to the hoplonemertines, the *secondary mouth* (1, 2, 3) develops as a lateral expansion of an ectodermal foregut which perforates to form a slit-like opening to the exterior. On the dorsal wall of the secondary mouth of hoplonemertines lies the proboscis, an organ for capturing food with prominent *glandular components* (4), and *muscular components* (5), which develops as an invagination toward and comes to lie inside the proboscis sheath-rhynchocoel complex. This complex is composed of a tubular multi-layered *muscular proboscis sheath* (6) surrounding a closed cavity filled with *rhynchocoel-fluid* (7) in which lies the flat muscular band, the *retractor* (8), extending from the posterior end of the sheath to the end of the proboscis. The proboscis develops armament composed of a *stylet base* (9) and a sharp *stylet* (10). Lying sometimes in, and sometimes ventral to, the proboscis sheath is the *dorsal vessel* (11), a major vessel of the *closed circulatory system* (12). The digestive tract may have a large ventral *gastric diverticulum* (13) and terminates in a definite *anus* (14). Sense organs may include inverse retina *lateral eyes* (15), *direct retina eyes* (16)⁸, *cerebral organs* (17), *onion-shaped organs* (18)⁹, and a *medial frontal organ* (19, 20) which lies on the dorsal anterior margin of the secondary mouth and may develop from a flat plate of ciliated ectodermal cells which invaginates as a groove. These sense organs and all muscles are connected by *solid nerves* (21) to a solid brain, composed of a pair of sensory *dorsal ganglia* (22) and a pair of motor *ventral ganglia* (23).

Each of the homologies suggested involves a number of specific positional, histological, and embryological similarities. In addition, the relations among structures of hoplonemertines are usually the same as those among the homologous structures of myxinoid cyclostomes. While a few resemblances between organisms can reasonably be explained by convergent

evolution, the large number of resemblances observed, the existence in an order of nemertines of homologues for major myxinoid structures, and similar relations among homologous organs can only be reasonably explained by phylogenetic affinity.

Accordingly, it is suggested that early myxinoids evolved from an early hoplonemertine by means of the following transformations. The secondary mouth was repeated serially to produce the three types of foregut apertures of myxinoids. The glandular proboscis failed to invaginate into the proboscis sheath-rhynchocoel complex and remained at the anterior end of that complex as the glandular pituitary. The muscular proboscis invaginated laterally along the proboscis sheath-rhynchocoel complex and was subdivided to form the enterocoelous somites. The rhynchocoel fluid became gelatinous and the proboscis sheath and retractor became non-contractile in forming the notochord. Only a single pair of lateral eyes was retained while these and other sense organs enlarged and differentiated. The frontal organ closed over at the neuropore and lengthened back over the notochord as a closed tube. This tube fused with the solid brain of nemertines to form the vertebrate tubular brain with alar and basal plates. This fused structure then lengthened back with replication of dorsal mixed and ventral proboscis motor nerves to form the spinal cord with dorsal mixed and ventral somatic motor nerves. The vestige of the original proboscis nerves remained as the neural hypophysis or infundibulum.

The phylogeny of the deuterostomes can be revised to be consistent with this hypothesis by considering primitive jawless fish to be the primitive deuterostome stock, from which other deuterostomes are derived by loss of sensory organs, specialization, and in some cases neotony¹⁰. Deriving the jawless fish from the hoplonemertines then connects the deuterostomes to a phylogenetic sequence beginning in the primitive protista ancestral to both plants and animals¹¹, and thereby delineates the early evolutionary history of man's own line (Fig. 1).

A paper detailing similarities between suggested homologues, discussing more fully the embryological similarities of nemertines and deuterostomes, outlining transitional stages, and comparing the present hypothesis with other current views of vertebrate origins is in preparation.

LETTERS TO THE EDITORS

PHYSICS

Impossible Magnetic-Field Self-Patterning

THE 'self-sustaining' Corbino disk recently proposed¹ is suspect. It was suggested that an axial magnetic field could Hall-deflect from an impressed radial current the azimuthal current just necessary for its existence. Inside, or axis side (outside, respectively), of an elemental current ring, its field contribution has indeed the sense of the field responsible for the ring, for inward (outward) motion of the dominant carriers. Outside (inside) the ring, however, its contribution is counter-sense to the field at the ring. This crucial embarrassment makes it difficult to imagine any finite, that is, physical, possibility for field self-patterning.

Certainly Midgley's solution, $B_z = Ar^{-k}$, $J_\theta = (k/\mu\eta_0) Ar^{-k-1}$, with neither changing sign, is trivial in the finite. In a disk with non-vanishing inner radius (finite radial current density) and finite outer radius, the fields at radii just within the inner and outer boundaries, lying inside and outside, respectively, all but an arbitrarily small circulating current, must differ in sign or both vanish. Thus A , the constant of integration, is zero. In an alternative view, the azimuthal current density, J_θ , must go the 'wrong' way just within the outer (inner) boundary, for inward (outward) motion of dominant carriers, unless J_θ vanishes identically.

Perhaps the one-dimensional formulation is insufficient. Specifically, the tacit neglect of the term $\partial B_r/\partial z$ in the θ -component of curl B is puzzling and possibly unjustified. One might have thought that, in the presence of azimuthal current, the radial component of the field would change considerably, and monotonically, along an axially directed path through a thin, but finite, current slab; and that at a true current sheet Maxwell's equation would not be applicable.

It should be stressed that only the theory of magnetic-field self-patterning in a finite, unencumbered Corbino disk has been considered here. No disparagement of the magnetic power amplifier or bi-stable trigger circuit suggested by Midgley is intended. Suitable biasing at the outer boundary, for example, might replace 'infinity'.

Self-patterning, or self-determining, fields (the terms 'self-sustaining' and 'self-maintaining' have unfortunate energetic connotations) are sustained (a) by exogenous current or (b) by current from motional induction within the system considered. In the light of impossibility theorems^{2,3} for certain simple classes of steady-state, magnetofluid-dynamic dynamos (type b), one might hypothesize that type-a self-patterning fields in cases of material homogeneity, high symmetry, and topological simplicity are unlikely to exist. For its own sake as a fundamental problem, and also for its possible relation to the important fluid dynamo problem under type b, the

question of the possibility of type-a self-patterning fields deserves closer attention.

³ Backus, G. E., and Chandrasekhar, S., *Proc. U.S. Nat. Acad. Sci.*, **42**, 105 (1956).

It is true that Cowling's impossibility theorem would apply to a finite and unencumbered disk. To achieve a non-zero solution, it is essential that a finite disk be encumbered to the extent of an input coil, or a magnetic feedback path as proposed in Fig. 2 of my communication. If such configurations of the magnetic field with more than one interlinkage of the electric circuit were admissible in the astronomical context, the difficulties of dynamo maintenance would be reduced.

The essentially one-dimensional solution is valid for a disk of finite thickness and permeability μ , bounded either by a medium of infinite permeability or by an axial stack of similar disks, such that $\partial/\partial z \equiv 0$. A finite disk not so bounded demands a more elaborate solution, in which B_r varies with z .

Short-Period Time Variations of Extensive Cosmic Ray Showers

AN exploratory experiment has been conducted to determine whether or not short-period fluctuations in the arrival of extensive showers are sufficiently systematic to warrant detailed study.

Two Geiger-Müller tubes 4 cm. in diameter and 40 cm. in length were connected in a coincidence circuit, and the output was recorded on an oscillograph with a paper speed of 5 mm./sec. The two tubes were placed parallel and were horizontally separated by 1 metre. The equipment was placed on the roof of a building free from obstructions. Two such equipments were operated independently. Approximately one count per minute was obtained.

A total of 60 records, 5 hr. in length, were studied. There were 30 such records for each equipment. The two equipments were separated by 12 and 330 m., so that the results obtained are regarded as independent samples.

The time-interval between successive counts, τ_i , was listed as a function of the serial number of the count, i . This provides about 300 data pieces per record. The auto-correlation function was computed for each record, and was afterwards used to obtain the spectral curve. If the time-interval between successive counts is independent of any preceding or succeeding such time-interval, the auto-correlation function should be identically zero for lags of one or

more. The corresponding spectral curve should be flat, analogous to white noise.

Twelve spectral estimates were obtained for each curve. The flat spectral curve analogous to that of white noise was subtracted from the observed spectral curve. It was assumed that each spectral estimate was independent of other spectral estimates in the same curve, and that positive and negative departures from the flat curve are equally likely. The twelve spectral estimates were divided into three groups corresponding to long, middle, and short periods. The number of records showing 0, 1, 2, 3, or 4 positive departures within a group was noted and compared with the expected number (see Table 1). The differences between the observed and expected results are statistically significant.

Table 1. NUMBER OF POSITIVE DEPARTURES FROM FLAT SPECTRAL CURVE

No. of +	I	II	III	Expected
0	13	5	18	4
1	12	13	9	15
2	14	18	19	22
3	11	14	9	15
4	10	10	5	4

Table 1 shows a tendency for all negative or all positive departures in group I, all positives in group II, and all negatives in group III. This suggests a maximum in the spectral curve near the boundary of group I and group II. The maximum corresponds to a periodicity in the range of 4-9 counts.

The experiment thus suggests that long time-intervals between successive counts tend to be followed by long intervals approximately 4-9 counts later. The average time-interval between counts was 74 sec., so that a systematic variation in the arrival of extensive showers is indicated in the range of 5-11 min.

Separation Factor of Tritiated Water Fractional in Distillation

A. H. PRICE has published¹ a table of values of vapour pressure of tritiated water. As these values differed greatly from our previous results, based on enrichment experiments of tritiated water in fractionating columns^{2,3}, it was decided to re-evaluate these results, taking into account our latest data of column operation⁴.

The unit process separation factor for tritiated water (THO) from ordinary water (H₂O), defined as the ratio of the concentration of tritiated water in the liquid phase to that in the vapour phase at equilibrium (at low concentrations), may be found from known concentrations at the top of a separation column and at the bottom of it or in the boiler. The general theory and detailed calculations were given by Dostrovsky *et al.*^{5,6}.

α_T is found from the relation :

$$N_B/N_E = \alpha_T \exp[(KZ/L)(\alpha_T - 1)] \quad (1)$$

where α_T is the separation factor for tritiated water ; N_B and N_E are boiler and reservoir concentrations of a batch-operated column ; K is transfer coefficient for vapour-liquid interface ; Z is length of column ; L is flow of liquid down the column.

The value of α_T reported by us previously was 1.055 ± 0.002 at 260 mm. mercury³. The values found from later experiments are given in Table 1.

Column Pressure (mm. mercury)	I	II	III
260	1.053 $\pm$ 0.002	1.051 $\pm$ 0.002	1.036 $\pm$ 0.001

These values are considerably smaller than the value of 1.13 found by Price¹.

It should be pointed out that for both pressures the ratio $(\alpha_T - 1)/(\alpha_D - 1)$ is 1.37 ± 0.02 .

The main source of error in our results is ascribed to the error in estimate of the values of KZ . These could not be measured directly and were calculated, using the enrichment values of tritiated oxygen in the same system. Inserting the known values of α_D into equation (1), the KZ values were calculated for each fractionating column.

The pressure in columns I and II was regulated by a manostat connected to a vacuum tank. The columns were tested for vacuum before each run. There was a pressure differential of 15 mm. between the boiler and the condenser and the average value was used. In column III the pressure differential was negligible.

The error resulting from pressure fluctuations was estimated to be small compared with other factors mentioned.

The tritium activity was determined in a Geiger-Muller counter measuring the activity of hydrogen obtained from reduction of water samples by zinc. This method has been found accurate to within ± 1 per cent for the measurement of relative activity. Deuterium concentrations were measured in a mass spectrometer.

The error quoted for α_T includes the above-mentioned errors, on the assumption, however, that values of KZ obtained from measurements on deuterium are valid for the determination of tritium enrichment.

Effect of Specular Reflexions on the Radiation Flux from a Heated Tube

In my communication under the above title¹ there appears an error in expression (7) for F_L' . The expression should read :

$$F_L' = \sigma T^4 \sum_{r=0}^{\infty} \epsilon^r (1 - \epsilon)^r \int_L^{\infty} \mu \left(\frac{h}{r+1} \right) dh$$

$$= \sigma T^4 \sum_{r=0}^{\infty} \epsilon^r (1 - \epsilon)^r (1 + r) \xi \left(\frac{L}{r+1} \right)$$

Taking the radiation from a black surface as reference, one can then show that the deficit from it of the flux of radiation from the mouth of a uniformly heated cylinder of length L , closed at the other end, is $(1 - \epsilon)$ times the corresponding deficit for the flux from the mouth of a cylinder of same diameter and of length $2L$, but open at both ends.

For the cylinder considered in the communication, which is closed at one end, and the length of which is five times its diameter, and the inner walls of which have an emissivity $\epsilon = 0.75$, the fraction $(1 - \epsilon)$ of the incident radiation that is not absorbed by the surface being specularly reflected by it, the flux of radiation across the mouth is found to be short of that from a black-body by only 0.23 per cent. As emphasized in the communication, the approach to black-body radiation holds over the whole of the 2π solid angle, unlike in the corresponding case when the walls of the cylinder have a matt surface.

Thus for a given emissivity the cylinder with specularly reflecting walls has a distinct advantage, as a source of black-body radiation, over one with a matt surface. For a given material, however, the effective emissivity will be markedly greater when the surface is matt than when it is polished.

GEOCHEMISTRY

Trace Element Relationships and Terrestrial Origin of Tektites

RECENTLY, Cherry, Taylor, and Sachs¹ reported from an examination of australite data "that silica concentration is significantly negatively correlated with the concentrations of aluminium oxide, ferrous oxide, magnesium oxide, potassium monoxide, and calcium oxide". Further, they suggest that tektite composition can be explained as the result of a mixing process between silica and some other material such as shale.

It would appear that the possibility of partial volatilization of several of the component oxides during formation of the tektite glass has not been considered by many workers in this field. If tektites were produced suddenly at temperatures near the boiling point of some of the components, then heavy losses of oxides more volatile than silica should follow. The silica content would also decrease somewhat from loss of SiO. Oxides of higher boiling point than silica, namely, aluminium oxide, ferrous oxide, magnesium oxide, and calcium oxide, would be enhanced in the resulting glass. This would account for the negative correlation of these oxides with silica without invoking a mixing of two materials such as shale and quartz. Recent work of Friedman, Thorpe, and Senftle² tends to confirm this point of view.

Table 1 compares three tektites of different ages but similar silica content with a quartz-porphyry of comparable silica content. It is seen that the tektites in general are higher in alumina, ferrous oxide, calcium oxide, and magnesium oxide and lower in

Table 1. COMPARISON OF COMPOSITION OF THREE TEKTITES FROM DIFFERENT FALLS WITH A QUARTZ-PORPHYRY

	1	2	3	4
SiO ₂	76.56	80.52	79.51	79.75

Col. 1, composition of an Ivory Coast tektite, analysis quoted by Barnes (ref. 3); col. 2, composition of a moldavite, analysis quoted by Barnes (ref. 3); col. 3, composition of an australite, analysis quoted by Barnes (ref. 3); col. 4, composition of a quartz-porphyry, analysis quoted by Iddings (ref. 4).

sodium oxide and potassium oxide than the igneous quartz-porphyry.

In order to test the proposition that tektites are produced at high temperatures and volatilization had taken place, the gallium/germanium ratios of a series of tektites and related terrestrial materials have been determined; the gallium oxide (Ga₂O₃) being less volatile and germania (as GeO) more volatile than silica (as SiO). Table 2 gives the results of some of these analyses. It is clearly seen that tektites have higher gallium/germanium ratios than terrestrial impactite glasses (Aouelloul glass, Darwin glass, and pumice glass, Cañon Diablo, Arizona), sand (Něchov, Czechoslovakia), and sandstones (Aouelloul sandstone, Cañon Diablo sandstone). That there is volatilization taking place in tektites is clearly brought out in the australite example where the second melting producing the flange has caused an increase in the gallium content over that found in the core. The Aouelloul impact glass shows an increase in gallium and decrease in germanium over the sandstone at the crater. Here the temperature was so intense that crystallites are absent in the glass. Darwin glass shows a higher germanium content than has been found in any tektite. In contrast to Aouelloul impact glass the pumice glass from Cañon Diablo crater did not reach a high enough temperature to form a compact glass and melt the coesite present (in the sample examined) and shows little change in Ga/Ge ratio. In confirmation of the work of Chao, Shoemaker, and Madsen³, the main crystalline constituent in this glass was found to be coesite (by X-ray diffraction). The tektites in general have gallium contents of 0.9–9.8 p.p.m. and germanium contents of 0.06–0.40 p.p.m. Analyses for a given tektite fall are consistent for cores.

The high temperature of formation of tektite glasses, the quenching of the melt before thorough mixing can take place, and the shapes (before secondary melting), all indicate that the formation of these glasses is from impact. As Urey has suggested⁴, a thorough search should be continued for explosion

Table 2. GALLIUM/GERMANIUM RATIOS OF TEKTITES, IMPACTITES AND RELATED MATERIALS

	Ga (p.p.m.)	Ge (p.p.m.)	Ga/Ge
Moldavite, Něchov, Czechoslovakia	3.1	0.15	21
Sand, Něchov, Czechoslovakia	9.6	1.64	6
Australite (core)	0.9	0.06	15
Australite (flange), same specimen	1.5	0.04	37
Aouelloul glass	4.7	0.67	7
Aouelloul sandstone	3.0	1.38	2
Darwin glass, Tasmania	2.6	0.53	4
Pumice glass, Cañon Diablo, Arizona	1.5	0.44	3
Sandstone, Cañon Diablo, Arizona	1.6	0.40	4
Tektite, Thailand	9.0	0.20	45
Indochinite, Delat, S. Annam	8.2	0.21	39
Tektite, Ivory Coast	9.8	0.35	28
Billitonite	8.2	0.40	20
Tektite, Anda, Philippine Islands	7.1	0.40	18
Javanite	4.6	0.34	14

craters large enough to account for tektite formation as a terrestrial event.

Mr. J. Anania and Mrs. S. A. Todd performed the analyses, and Dr. S. Pollack made the X-ray determination of coesite. Detailed publication of gallium/germanium ratios of additional tektites, meteorites, and related materials will be made elsewhere.

This work was carried out with the help of an N.A.S.A. Research Grant *NsG*-57-60.

CHEMISTRY

Crystallinity of Calcium Chondroitin Sulphate

WELL-DEFINED macroscopic shapes containing symmetry elements are generally regarded as a sign of crystalline arrangement of molecules. Recently, Kargin¹ demonstrated that polymer molecules might have a regular geometrical aggregate as viewed in the electron microscope without being crystalline so far as X-ray diffraction measurement is concerned and vice versa. In our work with calcium chondroitin sulphate *A* we encountered apparently a similar phenomenon. Einbinder and Schubert² reported that calcium chondroitin sulphate (their so-called mid and tail fraction) showed crystalline shapes under the microscope when precipitated with ethanol from aqueous solution. These same fractions, however, proved to be amorphous in our X-ray diffraction experiments. Further investigation also revealed that the 'head' fraction of calcium chondroitin sulphate which Einbinder and Schubert² reported as amorphous under the microscope was highly crystalline in X-ray diffraction studies. Detailed analysis of these results will be reported elsewhere.

All three fractions of calcium chondroitin sulphate *A* were isolated from acetone-dried bovine trachea according to the method *A*₂ of Einbinder and Schubert² (extraction with aqueous potassium chloride and potassium carbonate, repeated purification with kaolin, dialysis, precipitation of the potassium salt and finally conversion to calcium salt). The yield was comparable to that reported previously. However, the crystalline 'head' fraction had a high ash content, and further purification was necessary. This was achieved by redissolving this fraction in distilled water, centrifuging at 6,000 r.p.m. for 20 min. and precipitating the supernatant with 3 vol. of absolute ethanol. Only about 10 per cent of the original head fraction was recovered this way. This new isolated head fraction was highly crystalline and had the following micro-analysis: C = 33.34 per cent, H = 6.08 per cent, N = 2.96 per cent, S = 2.05 per cent, Ca = 2.70 per cent. The theoretical value for a new type of calcium chondroitin sulphate which is sulphated only at every third chondroitin unit with 5 moles of water of hydration per chondroitin

(C₁₁O₂₂H₁₁N₂SO₄Ca.15H₂O) would be C = 33.02 per cent, H = 6.03 per cent, N = 2.75 per cent, S = 2.09 per cent, and Ca = 2.62 per cent.

The middle and tail fractions of calcium chondroitin sulphate *A* had the following microanalysis:

	C	H	N	S	Ca
Mid	27.95	5.49	2.81	4.90	5.99
Tail	28.09	5.50	2.81	4.46	6.00
Theoretical of repeating unit of calcium chondroitin sulphate <i>A</i> (C ₁₁ H ₁₁ N ₂ SO ₄ Ca.5H ₂ O)	28.61	4.98	2.39	5.45	6.81

All three fractions indicated the same two spots on paper chromatography of their acid hydrolysate: glucuronic acid and galactosamine. Infra-red absorption spectra of the fractions were taken by a double-beam Beckman IR-7 spectrophotometer on films of 0.02 mm. thickness. The infra-red spectra of the middle and tail fractions were identical, and, therefore, only one is reproduced in Fig. 1. On the other hand, the head fractions showed distinct differences. The most important among these are the absence of the sulphate band at 725 cm.⁻¹ and the shift of the band from 928 to 955 cm.⁻¹. Similarly the sulphate band^{3,4} at 1,240 cm.⁻¹ has greater intensity in the tail fraction than in the crystalline head fraction. The band between 1,000 and 1,150 cm.⁻¹ is broader in the case of the crystalline fraction, possibly indicating hydrogen bonding of primary and secondary alcohols with other polar groups which is lessened if the polymer chain is more highly sulphated (tail fraction).

Fig. 1. Infra-red absorption spectra of the head fraction (—) and the tail fraction (---) of calcium chondroitin sulphate from bovine trachea

One might come to the general conclusion with respect to structure and crystallinity among the chondroitin sulphate isomers as follows: the crystalline 'head' fraction is a calcium chondroitin sulphate polymer sulphated only at every third chondroitin moiety, as both infra-red and microanalysis indicate. Due to the fact that this fraction went through only the mildest additional treatment (centrifuging and reprecipitating) it is unlikely that this is an artefact of the preparation. The intrinsic viscosity in 0.1 *M* sodium chloride solution of this fraction was the lowest, 0.22 dl./g., compared with 3.09 dl./g. of the middle fraction and 0.9 dl./g. of the tail fraction. Its precipitation with the smallest concentration ethanol also indicates that the head fraction is less polar than the other two fractions which are actually precipitated according to their molecular weights.

Fig. 2. Electron micrographs of calcium chondroitin sulphate precipitated with ethanol from aqueous solution. Platinum shadow casting. Black lines indicate 1μ . Top, head fraction; middle, mid fraction; bottom, tail fraction

Thus it seems plausible that the frequent and bulky side groups of sulphate prevent crystalline alignment of the chains, and one gets ordered polymer regions only when the degree of sulphation is reduced together with shorter polymer chains.

In the light of the above conclusion we wanted to investigate whether Kargin's observation can apply to chondroitin sulphate, that is, whether the micro-

scopic structure has anything to do with the molecular organization. Electron micrographs were taken with an RCA EMU 2B electron microscope under conditions described previously³. The three fractions isolated were dissolved in distilled water and reprecipitated in ethanol, and a loopful of the colloidal suspension was placed on a screen 15 min. after the addition of ethanol and shadowed with platinum. The electron micrographs are shown in Fig. 2.

The head fraction, which showed high crystallinity in X-ray diffraction, formed sheet-like aggregates sometimes with well-defined edges. This is not unlike those electron microscopic structures one observes in polycrystalline synthetic high polymers such as polyethylene.

The higher-molecular weight calcium chondroitin sulphate A (mid fraction), which was completely amorphous in X-ray diffraction, showed also completely amorphous aggregation in the electron microscope.

The tail fractions aggregated in shapes similar to those observed by Einbinder and Schubert². These aggregates had orderly regions comparable to liquids only as viewed by X-ray diffraction. Still, there was a certain amount of symmetry although they lacked the higher symmetry elements of crystals. Probably this was a fraction with low enough molecular weight to provide anisotropic chains for orientation, but still having enough bulky side-groups to prevent orderly alignment. This, therefore, may represent Kargin's transition group between geometrical crystallinity and the completely amorphous state.

This research was supported by a grant (C-3984 BBC) of the National Cancer Institute, Public Health Service.

Preparation of Silver Iodide Sol by Ion-exchange Resin

WHEN preparing a silver iodide sol by mixing solutions of silver nitrate and potassium iodide:

the electrolyte potassium nitrate has to be removed.

The use of electrodialysis is a very elaborate process, so the obvious thing is to replace it by ion-exchange resins.

This method has two drawbacks:

(1) a strongly basic anion-exchange resin adsorbs part of the sol particles;

(2) a weakly basic resin gives organic impurities to the sol.

My experiments showed that extracting the resin with water in a Soxhlet for 24 hr. is sufficient to remove these impurities completely.

This effect is clearly demonstrated by the conductivity of the effluent water of the ion-exchange columns of extracted and non-extracted resin respectively.

Table 1

$\sigma \times 10^{-6} \Omega^{-1} \text{ cm.}^{-1}$ effluent water	Before	After
Strongly acid resin	20	2-4
Weakly basic resin	20-200	2-4

Solutions of 200 m.mol. silver nitrate/l. and 220 m.mol. potassium iodide/l. (10 per cent excess) were used. The strongly acid exchange resin was 'Amberlite IR 120 H', the weakly basic 'Amberlite IR 45'.

The sol mixture was first sent over the strongly acid resin, the weakly basic reacting only in the pH interval 0-7.

By this method an 80 per cent yield of sol was obtained, with a conductivity of $\sigma = 2$ to $3 \times 10^{-5} \Omega^{-1} \text{ cm.}^{-1}$.

Oscillographic Polarography of Highly Polymerized Deoxyribonucleic Acid

PROCEEDING from my finding^{1,2} that nucleotides, nucleosides and the bases of nucleic acids can be analysed by alternating current oscillographic polarography³⁻⁵, I have also tried to study polymerized deoxyribonucleic acid by this method.

The apparatus used was a Polaroskop P 524 (Křizík, Praha). With this apparatus it is possible to plot dE/dt against E (Fig. 1). The analysis was carried out by means of the dropping mercury electrode in the same electrolytes as were used in my previous work^{1,2}. All measurements were carried out with specimens of deoxyribonucleic acid from calf thymus.

I have established that in a medium of molar ammonium formate, deoxyribonucleic acid shows an

Fig. 1. Graph of dE/dt against E . The nature of the material analysed is characterized by the potential of the indentation (PC), which is somewhat similar to the polarographic half-wave potential. The quantity of the material is characterized by the depth of the indentation. For qualitative analysis, the height II , which can be measured much more easily, is generally measured. K , Cathodic part; A , anodic part

anodic indentation at the same potential as deoxyguanylic acid (Fig. 2). Other characteristics of both indentations are also analogous (dependence on direct voltage, temperature, concentration of the electrolyte), which appears to indicate that that due to deoxyribonucleic acid is brought about by deoxyguanylic acid bound in the molecule of deoxyribonucleic acid. In order to verify this observation, I removed the adenine and guanine from the deoxyribonucleic acid molecule by treating it with dilute hydrochloric acid (pH 1.6, 37°C.)⁶, and analysed the apurinic acid obtained in this way by oscillographic polarography in ammonium formate as medium. No characteristic anodic indentation was observed on the oscillogram; but, on the contrary, a new cathodic indentation was formed approximately in the same region where an indentation is produced by deoxycytidilic acid under similar conditions (Fig. 3). This indentation is shown even after drastic denaturation of deoxyribonucleic acid and, in fact, becomes deeper.

Thus in non-denaturated deoxyribonucleic acid, deoxyguanylic acid reacts oscillo-polarographically,

Fig. 2. 100 $\mu\text{gm.}$ deoxyribonucleic acid/ml. 1 M ammonium formate

Fig. 3. Apurinic acid in 2 M ammonium formate (concentration corresponding to 2 mgm. of deoxyribonucleic acid)

Fig. 4. 900 $\mu\text{gm.}$ deoxyribonucleic acid + 5 $\mu\text{gm.}$ plasma albumin/1 ml. $10^{-3} M$ hexamine cobaltic trichloride in 0.1 M ammonium chloride-ammonium hydroxide. Indentations due to cobalt, I; deoxyribonucleic acid, II; protein, III

whereas deoxycytidylic acid bound in its molecule is inactive. This phenomenon may be perhaps interpreted in the following manner: one part of the guanine purine ring, which is of great importance for the formation of the anodic indentation (apparently an amino-group in position 2 is involved³), is found in the molecule near the surface, whereas the analogous part of the pyrimidine ring of cytosine (apparently the 6-amino-group³) is hidden inside the molecule where it participates in the formation of the hydrogen bond. In apurinic acid, where the double-helical structure is completely destroyed, deoxycytidylic acid is not blocked sterically in any way so that its oscillo-polarographic activity may manifest itself. Free deoxyadenylic acid and deoxythymidylic acid do not show the characteristic indentation in ammonium formate as medium, and consequently no indentations due to these nucleotides can be expected if they are bound in the molecule of deoxyribonucleic acid.

I have also studied deoxyribonucleic acid and apurinic acid in 2 *M* sodium chloride as medium; both substances yield oscillograms that differ only slightly. In 1 *M* sodium hydroxide, the oscillograms of deoxyribonucleic acid differ considerably from those of apurinic acid.

In cobalt and nickel solutions⁷, proteins give an indentation even at a very low concentration⁸. Since the deoxyribonucleic acid indentation is produced in this medium at a different potential, I was able to use the oscillopolarographic reaction for detecting deoxyribonucleic acid and proteins in the presence of each other. In this manner, proteins can be detected even in the presence of an abundance of deoxyribonucleic acid (Fig. 4).

Fluorescence of Organic Traces in Inorganic Substances

In previous publications¹ I have directed attention to the fluorescence due to traces of organic substances in commercial inorganic chemicals and in minerals. What was not clear was the relation of my experiments to the somewhat similar ones of Ewles². Recent investigations have now convinced me that we were observing two quite different phenomena. This is best shown by the following experiments:

(1) Exciting alumina (Merck, for chromatography) with 254 mμ, I obtain fluorescence that is not enhanced by weak annealing and not destroyed by 1 min. at red heat, and also phosphorescence, in perfect agreement with Ewles, who had to heat his samples for hours at high temperatures to get rid of

the fluorescence. I find, however, that the phosphorescence no longer appears after 1 min. at red heat and is not regenerated by adding traces of organic substances.

(2) On the other hand, on exciting alumina which has been exposed to atmospheric dust with 365 mμ, there is no noticeable phosphorescence, and the fluorescence is enhanced by weak annealing, destroyed by 1 min. at red heat and regenerated by weak annealing after adding traces of organic substances.

Under condition (1) we have the Ewles effect: luminescence of adsorbed water or other substances containing the OH-group; under condition (2) fluorescence of organic traces occurs.

The latter, frequent in minerals, has now also been found in certain meteorites: Hvittis (Finland), Stannern (Moravia); it remains to be seen if these have acquired traces of organic substances after their arrival on the Earth or already in outer space.

Triphosphitochromic Acid

TRIVALENT chromium forms, with dibasic anions of oxygen-containing acids, complex ions of the type $[\text{Cr}(\text{AA})_2]^{2-}$, in which the ligands are bound to the central atom through oxygen atoms. The best-known representatives of this group of compounds are trisulphatochromates(III)^{1,2} and complex anions with organic acids³, for example, with oxalic^{4,5} and lactic⁶ acid. The complex with lactic acid is the stable and relatively strong trilactatochromic acid $\text{H}_2[\text{Cr}(\text{Lact})_2]$. The phosphite anion, which may also act as a bidentate oxoligand⁷, forms a similar triphosphitochromic acid $\text{H}_2[\text{Cr}(\text{HPO}_3)_2]$.

Free triphosphitochromic acid can be prepared in crystalline form by dissolving freshly precipitated chromic hydroxide (precipitated by ammonia at pH ~8) in a boiling aqueous solution of phosphorous acid, followed by crystallization. The decahydrate of triphosphitochromic acid is obtained, forming green crystals soluble in water and methyl alcohol, practically insoluble in ethyl alcohol and ether, of density 2.03 at 20° C. The complex is paramagnetic, having a molar magnetic susceptibility of 7.8×10^{-3} at 20° C. The compound liberates its ten water molecules at 40° C. The conductometric and pH metric titration of triphosphitochromic acid solutions by sodium hydroxide show that the compound prepared is a tri-basic acid ($K_1 \sim 2 \times 10^{-2}$, $K_2 \sim 4 \times 10^{-6}$, $K_3 \sim 4 \times 10^{-7}$) and forms sodium and ammonium salts easily soluble in water, and salts of alkaline earths, transition and heavy metals which are only slightly soluble. The ammonium salt $(\text{NH}_4)_3[\text{Cr}(\text{HPO}_3)_2] \cdot 6\text{H}_2\text{O}$, sodium salt $\text{Na}_3[\text{Cr}(\text{HPO}_3)_2] \cdot 4\text{H}_2\text{O}$ and barium salt $\text{Ba}_3[\text{Cr}(\text{HPO}_3)_2] \cdot 8\text{H}_2\text{O}$, have been prepared in the crystalline state. Aqueous solutions of the acid and its salts show, as may have been expected, reducing properties, and reduce, for example, after standing for some time, silver salts to metallic silver. The reduction, however, takes place much more slowly than with the free, non-complex phosphite anion.

Similarly to the trioxalatochromic anion⁵, the triphosphitochromic anion must also, because of its proposed structure, have optical isomerism. This has been proved experimentally by transforming triphosphitochromic acid via the tri-*d*-strychnine salt to optically active sodium *d*-triphosphitochromate(III). Compounds containing the triphosphitochromic anion in one of its stereoisomeric forms, however, are rapidly autoracemized in aqueous solution, so that it has been impossible to determine the value of molecular rotation, or to separate the other stereoisomer. The triphosphitochromic anion is, however, interesting by the fact that it is a further representative of the, as yet very rare, type of purely inorganic (that is, carbon-free) optically active compound.

The determination of the instability constant of the triphosphitochromic anion, which has been carried out by pH-measurements and by spectrophotometric methods, has shown that the anion is highly complex ($K \sim 2 \times 10^{-11}$); this is surprising because of the presence of three four-membered rings in the molecule. In some analytical reactions, masking of chromium is, in fact, observed. It is, for example, impossible to precipitate either chromic hydroxide or phosphate from solutions of the triphosphitochromic anion.

In comparison with the other anionic oxo-complexes of trivalent chromium, the free acids of which are known either only in dilute solutions (trilactatochromic acid or other complexes with organic acids), or are not defined in the crystalline state (trisulphatochromic acid), or lastly are totally unknown in the free state (trioxalatochromic acid), the triphosphitochromic anion is remarkable for the fact that free triphosphitochromic acid is stable and well defined even in the crystalline state.

BIOCHEMISTRY

Effects of α -Lipoic Acid on the Respiratory Chain of Plant Mitochondria

THIS communication describes the effects of oxidized α -lipoate (6:8-dithio-*n*-octanoate) on the respiration and oxidative phosphorylation of mitochondria isolated from red beetroot (*Beta vulgaris* L.)¹. Both spectrophotometric (Table 1) and manometric

Table 1. EFFECTS OF OXIDIZED LIPOATE ON ENZYMIC ACTIVITIES OF MITOCHONDRIA FROM BEETROOT

Substrate	Oxidant	Enzymic activities*	
		Control	With lipoate (0.1 mM)
Reduced coenzyme I (0.13 mM)	oxygen†	0.67	0.17
	ferriocytochrome c (60 μ M)	3.77	1.18
	dye ‡ (65 μ M)	6.73	4.53
Malate (50 mM)	ferriocytochrome c (60 μ M)	0.29	0.08
Malate (50 mM) plus coenzyme I (0.13 mM)	ferriocytochrome c (60 μ M)	0.87	0.14
Succinate (50 mM)	ferriocytochrome c (60 μ M)	0.34	0.81
	dye‡ (65 μ M)	1.25	1.26
Ferriocytochrome c (60 μ M)	oxygen†	5.44	9.73

* Changes in extinction were determined spectrophotometrically at 340 m μ for coenzyme I, at 550 m μ for cytochrome c, and at 600 m μ for 2,6-dichlorophenol indophenol. Results are expressed as $\Delta E/\text{min.}/\text{mgm.}$ of mitochondrial nitrogen at room temperature (about 25° C.), for 3 ml. of reactants in 1-cm. cells.

† Solutions were equilibrated with air.

‡ 2,6-dichlorophenol indophenol.

(Table 2) results showed that added lipoate (0.1 mM) caused substantial inhibition of the oxidation of reduced coenzyme I and of coenzyme I-linked substrates with oxygen, ferriocytochrome c and 2:6-dichlorophenol indophenol as oxidants. However, the oxidation of succinate was not inhibited by lipoate at 0.1 mM concentration (Table 1). Lipoate caused a marked stimulation (about 100 per cent) of the succinate-cytochrome c reductase activity of mitochondria modified by freezing and thawing or by exposure to hypotonic conditions.

As shown in Table 2, esterification of inorganic phosphate was more strongly inhibited by added lipoate than was substrate oxidation. Other results with α -ketoglutarate and with pyruvate as substrates suggest that the substrate-level phosphorylation may not be inhibited. Lipoate had little effect on the adenosine-triphosphatase activity of beetroot mitochondria with or without added magnesium chloride.

Sodium arsenite (1 mM) did not affect the inhibition of the oxidation of reduced coenzyme I caused by oxidized lipoate, whereas it prevented a small progressive inhibition caused by reduced α -lipoate (6:8-dimercapto-*n*-octanoate). The action of the dimercaptan is attributed to progressive formation of oxidized lipoate. The effects shown in Tables 1 and 2 do not appear to involve dimercaptan formed enzymically in the mitochondria.

The effects shown in Tables 1 and 2 could not be duplicated with short-chain fatty acids (*n*-valerate, *n*-caprate, *n*-caprylate, *n*-caproate), nor with cysteine, cystine, oxidized glutathione or 2:3-dimercaptopropanol (BAL). Although the oxidation of reduced coenzyme I was inhibited (56 per cent) by BAL (10 mM), the presence of BAL did not interfere with the inhibitory effect of oxidized lipoate. Bovine serum albumin (0.17 per cent), but not ethylenediamine tetraacetate or ascorbate, prevented the inhibitory effect of lipoate on the oxidation of reduced coenzyme I; presumably albumin binds lipoate. Cystine (0.1 mM) caused an inhibition (60 per cent) of cytochrome c oxidase activity in contrast to the stimulation caused by lipoate (Table 1).

Table 2. EFFECT OF OXIDIZED LIPOATE ON OXIDATIVE PHOSPHORYLATION CATALYSED BY MITOCHONDRIA FROM RAD BEETROOT*

Expt.	Substrate	Control			With lipoate			
		$Q_{O_2}^N$	P/N	P/O	Lipoate concentration	$Q_{O_2}^N$	P/N	P/O
1	α -ketoglutarate (50 mM) + malonate (50 mM)	225	43.6	2.95	0.5 mM	26.0	1.1	1.03
2	Malate (50 mM)	149	24.9	1.87	0.1 mM	50	5.8	1.34
					0.5 mM	16	0.8	0.56
	Malate (50 mM) plus coenzyme I (0.48 mM)	195	31.4	1.80	0.1 mM	54	5.5	1.14
					0.5 mM	34	0.7	0.24
3	Succinate (50 mM)	441	41.3	1.05	0.1 mM	455	23.5	0.58
					0.5 mM	177	0	0
4	Malate (50 mM)	241	23.6	1.64	0.1 mM	91	5.4	1.00
	Malate (50 mM) plus 2,4-dinitrophenol (0.1 mM)	224	—	—	0.1 mM	74	—	—

* Measurements were carried out manometrically at 25° C.; the esterified phosphate was estimated as glucose-6-phosphate as previously described (ref. 1).

$Q_{O_2}^N$ is μ litres of oxygen/hr./mgm. of mitochondrial nitrogen.

P/N is μ moles of orthophosphate esterified/hr./mgm. of nitrogen, and P/O is ratio of moles of orthophosphate esterified to atoms of oxygen consumed.

The effects of lipoate were quite different from those obtained with other respiratory chain inhibitors^{1,2} such as amytal, antimycin A and 2-hydroxy-3-(2-methyloctyl)-4-hydroxyquinoline-N-oxide and no competitive or synergistic effects were observed when each of these compounds was added with lipoate. Whereas oxidized lipoate had little effect on succinate-cytochrome c reductase activity of fresh mitochondrial preparations (Table 1), antimycin A and 2-hydroxy-3-(2-methyloctyl)-4-hydroxyquinoline-N-oxide were strongly inhibitory^{1,2}. However, prolonged incubation with oxidized α -lipoate particularly at 0.5 mM concentration, caused inhibition of the succinate-cytochrome c reductase and of succinate oxidase (see Table 2). Oxidized lipoate also differed from amytal in causing a somewhat similar inhibition of oxidation of reduced coenzyme I with either ferricytochrome c or 2,6-dichlorophenol indophenol as oxidant (Tables 1 and 3).

Extinction changes measured at 520 $m\mu$ showed that lipoate at 0.1 mM had little effect on the swelling of freshly isolated mitochondria. However, a pronounced effect was obtained at 0.5 mM lipoate. The swelling was enhanced by the addition of substrates and was reversed with adenosine triphosphate (5 mM) plus magnesium chloride (3 mM) and prevented with bovine serum albumin (0.17 per cent). However, the effects of lipoate on the enzymic systems of both beetroot mitochondria damaged by hypotonicity or

by freezing, and optically clear suspensions obtained by treatment of mitochondria with sodium deoxycholate, were similar to the effects observed with intact mitochondria. Thus the lipoate-induced swelling does not account fully for the effects shown in Tables 1-3.

Similar effects to those shown in Tables 1 and 2 have been obtained with mitochondria isolated from wheat roots, silver-beet petioles, cauliflower buds and pea cotyledons. The aerobic oxidation of reduced coenzyme I by rat-liver mitochondria was inhibited (50 per cent) by lipoate (0.1 mM). The effects on other enzymic systems of animal mitochondria are being further studied.

The effects of lipoate described here do not appear to involve the coenzyme function of lipoate in the oxidative decarboxylation of α -keto acids. The stimulation of cytochrome c oxidase, the induced swelling and the activation of succinate-cytochrome c reductase may all reflect the ability of lipoate to form a complex with lipoproteins. The inhibition of coenzyme I oxidation (Table 1) and the uncoupling of phosphorylation (Table 2) are more clearly associated with the disulphide bond of oxidized lipoate. Lipoate appears to act on, or very close to, the dehydrogenase which activates coenzyme I (Tables 1 and 3). Reduced coenzyme I-cytochrome c reductase as extracted from heart muscle mitochondria is a flavoprotein which requires intact sulphydryl groups for activity^{3,4}. Recently, Green and co-workers⁵ found that this enzyme is inhibited by 1 mM concentrations of dimercaptans (BAL, lipoate and lipamide) which would have been rapidly oxidized. Dixon *et al.*⁶ have recently found that the enzyme is inactivated by oxygen with concomitant displacement of the flavin prosthetic group, possibly due to oxidation of —SH groups of the enzyme (see ref. 7).

It is suggested that the inhibition of the respiratory chain oxidation of reduced coenzyme I (Tables 1-3) is due to inhibition of the primary dehydrogenase by oxidized lipoate which may enter into

exchange reactions⁸, with sulphydryl groups essential for the dehydrogenase activity. The uncoupling of oxidative phosphorylation by lipoate may be due to a

A Factor in Agar which reverses the Antibacterial Activity of 1-Methyl-3-nitro-1-nitrosoguanidine

WHILE working with 1-methyl-3-nitro-1-nitrosoguanidine, an anticancer agent in mice^{1,2} and an antibacterial agent *in vitro*, we observed that Difco agar contained a factor which inhibited the activity of 1-methyl-3-nitro-1-nitrosoguanidine against *Escherichia coli* strain S. The activity of this compound was tested by the filter paper disk-assay method on minimal³ medium pH 6.8, containing 2 per cent agar. The zones of inhibition were smaller when the medium was sterilized by steaming for 20 min. than when sterilized by autoclaving (15 lb./sq. in.) for the same length of time (Table 1). Several lots of Difco agar had the same property, but other commercially available agars did not. These latter agars are: BBL (Baltimore Biological Laboratory), NBC (Nutritional Biochemical Co.), 'Ton Agar No. 2' (Oxo, Ltd., London), and Difco 'Noble Agar'.

Difco agar was freed of the factor by extraction with water or methyl alcohol, but not with ethyl alcohol, acetone, or butanol. The aqueous or methanol extracts (vacuum dried and reconstituted in water) reversed the effect of 1-methyl-3-nitro-1-nitrosoguanidine when added to liquid cultures and assayed

turbidimetrically. Aqueous extracts lost all activity within 24 hr. at room temperature, but were stable for at least four weeks at -10°C .

The activity of 1-methyl-3-nitro-1-nitrosoguanidine is reversed by amino-acids, —SH compounds, methylamine and ascorbic acid (personal observation). The active extracts were ninhydrin-negative. Polarographic analysis revealed no —SH or S—S compounds. There was no detectable amount of ascorbic acid. The factor did not absorb ultra-violet light.

Compounds with biological properties similar to 1-methyl-3-nitro-1-nitrosoguanidine were tested for their response to the agar factor. The antibacterial activity of 11 nitrosoguanidines, differing only in the alkyl substituent on N-1, was reversed. Only 1-chloroethyl-3-nitro-1-nitrosoguanidine was not reversed even though the analogous compounds, 1-ethyl and 1-chloropropyl-3-nitro-1-nitrosoguanidines, were reversed. The activity of 1-nitroso-2-nitramino-2-imidazoline, a condensed nitrosoguanidine, and of 5-diazouracil was reversed, but that of nitrogen mustard, azaserine, 'Mitomycin C', β -propiolactone, 4-nitroquinoline-N-oxide was not. The agar factor had no effect on the antibacterial activity of penicillin, streptomycin, or aureomycin.

There is in Difco agar a water- and methanol-soluble, heat-unstable substance which reverses the antibacterial activity of the anticancer agents, 1-alkyl-3-nitro-1-nitrosoguanidines and 5-diazouracil. The isolation and identification of this factor might be helpful in elucidating the mechanism of action of these compounds.

A New Approach to the Study of Thiamine Deficiency

IT is well known that dietary deficiency of thiamine impairs normal carbohydrate metabolism because of the role of co-carboxylase as coenzyme in the oxidative decarboxylation of pyruvate and α -ketoglutarate¹, and the transaldolation and transketolation² of aldoses and ketoses, which inhibit the liberation of the energy necessary to maintain tissue in its living state. Also, it has been shown that fat has a sparing action on the thiamine³; but little is known concerning protein metabolism in this form of avitaminosis.

Re-investigation⁴ of this problem has shown that glyoxylic acid, a metabolic intermediate, arises from excessive breakdown of tissue protein; by radioactive isotopic tracer study, the origin of this acid was proved to be glycine. The presence of glyoxylic acid in normal animals is transient, since it can be reconverted into glycine or further metabolized into formate and then into carbon dioxide and water, or it can be excreted in the urine.

‡ Baltimore Biological Laboratory, Baltimore, Maryland.

However, in animals deficient in thiamine, difficulties arise in the disposal of the glyoxylic acid. A block occurs in its enzymatic oxidative decarboxylation to formate, due to the absence of co-carboxylase⁵; as a result, various tissues may be affected by its cumulative toxic effect. The kidneys gradually lose their capacity to eliminate this acid, and thus aggravate its detrimental effect on all tissue metabolism. The syndrome seen in experimental animals is similar to the clinical findings in cases of thiamine deficiency.

It has been shown not only that fat spares thiamine, but also that a possibility exists that fat may provide ample amounts of acetyl-coenzyme A to condense with glyoxylic acid to form malate, thus annulling the detrimental effects of the glyoxylic acid. It has been suggested also that the glyoxylic acid condenses with a 4-carbon Krebs cycle intermediate to compete for the aconitase dehydrogenase system⁶.

The present work also indicates that it cannot be assumed that an animal deficient in thiamine follows the same metabolic patterns as a normal animal, except for its inability to utilize carbohydrate properly. The whole metabolic pattern is altered, and it changes and shifts continually in order to fulfil the necessary energy requirements under this abnormal condition. The results indicate that the interdependency of the metabolism of carbohydrate, fat and protein is responsible for the underlying causes of this phenomenon.

A detailed account of this work will be published in due course.

Re-assessment of the Stoichiometry of Photophosphorylation

THE light-induced phosphorylation of adenosine diphosphate to adenosine triphosphate by chloroplasts is associated with, and presumably coupled to, a transfer of electrons. In most of the systems investigated water has been the electron (or hydrogen) donor, and flavin mononucleotide, vitamin K₃, ferricyanide or triphosphopyridine nucleotide has been the electron (or hydrogen) acceptor. The early work was carried out on systems involving flavin mononucleotide or vitamin K₃ or both. Unfortunately the reduced forms of these substances are readily re-oxidized by molecular oxygen, and this re-oxidation of the electron acceptor by the oxidized electron donor resulted in a cyclic process in which the electron flux could not be measured. Consequently the stoichiometry of the reaction or reactions forming adenosine triphosphate could not be established. However, with the discovery that phosphorylation also accompanied the reduction of substances the reduced forms of which were not re-oxidized, this difficulty disappeared. Both Arnon

and his associates¹ and Avron and Jagendorf² reported that one mole of adenosine triphosphate was formed for every two moles of electrons transferred in the reduction of ferricyanide or triphosphopyridine nucleotide. This stoichiometry has been widely quoted.

I have confirmed the observations of these workers. Indeed in 36 determinations involving ferricyanide reduction, it was found the ratio of adenosine triphosphate to electron pairs transferred was 1.00, with a standard error of the mean of only ± 0.017 . Moreover, a similar stoichiometry for flavin reduction and adenosine triphosphate formation has been observed when precautions were taken to trap the hydrogen peroxide formed by the reaction of oxygen with reduced flavin mononucleotide³. Nevertheless, there are the following reasons for believing that this rather precise ratio of 1.00 is fortuitous and without biological significance.

(1) Unless the mechanisms coupling oxido-reductions to phosphorylation are exceedingly complex, the ratio of adenosine triphosphate to the electron pairs must be represented by a whole number. An experimental average of precisely unity suggests that the theoretical maximum is probably higher, since to establish the validity of a larger ratio, such as 2, it need only be established that any one experimental value is truly in excess of unity. On occasion, values of the ratio consistently greater than unity have been obtained, in spite of the fact that there are certain to be some biological and assay losses of adenosine triphosphate.

(2) The reduction of ferricyanide, triphosphopyridine nucleotide or flavin mononucleotide by illuminated chloroplasts can proceed in the absence of phosphorylation. The presence of optimal amounts of adenosine diphosphate, orthophosphate and magnesium ions increase this 'basic' rate two- to three-fold. Therefore chloroplasts isolated by the methods currently employed must be equipped with a mechanism for electron transfer which is not coupled to phosphorylation. Obviously any electrons carried by this mechanism must be subtracted from the total flux before the stoichiometry of the reaction, which does involve phosphorylation, can be computed. Unfortunately, we only know with certainty the extent of this basic, non-phosphorylating process in the absence of phosphorylation; the simultaneous activity of the phosphorylating system might alter or almost abolish the 'uncoupled' reaction. Krogmann, Jagendorf and Avron⁴ recognized the need to evaluate the competition between the systems, but were unable to come to any conclusion on the basis of the evidence then available. The new evidence presented below can be best interpreted by assuming the continuing existence of most of the basic, non-phosphorylating electron transport at all degrees of activation of the phosphorylating system. Consequently a revision of current estimates of the stoichiometry of the phosphorylating reaction is indicated.

Chloroplasts from the leaves of young pea plants were isolated, washed once and re-suspended in an ice-cold buffer consisting of 135 gm. sucrose, 3.0 gm. *tris*(hydroxymethyl)aminomethane and 1.0 gm. sodium chloride per litre, adjusted to pH 7.95 with sulphuric acid. An amount of this suspension containing about 50 μ gm. chlorophyll was placed in a 1-cm.² cuvette with buffer, adenosine triphosphate (5×10^{-4} M), magnesium sulphate (3×10^{-3} M), hexokinase (1.3 mgm.), glucose (1.5×10^{-2} M) and 1.0 μ mole potassium ferricyanide. Dipotassium hydrogen phosphate labelled with phosphorus-32 was added in

various amounts giving final concentrations from $5 \times 10^{-4} M$ to $2 \times 10^{-3} M$. Total volume of the reaction mixture was 2.0 ml. Ferricyanide reduction was followed spectrophotometrically in an apparatus described elsewhere⁶. The formation of adenosine triphosphate was measured by the method of Nielsen and Leninger⁶. The chloroplasts were illuminated by red light at intensities well above saturation.

The levels of phosphate employed stimulated the rate of ferricyanide reduction from about 10 per cent to approximately 250 per cent. The rate in the absence of phosphate was re-determined every few minutes. By subtracting this rate from the rates observed with the various phosphate concentrations, rates were obtained which were attributed to the phosphorylating process. A proportion of the total ferricyanide reduction was thereby somewhat arbitrarily assigned in each case to the phosphorylating process. Obviously, if this procedure is valid, a linear relationship between the amount of adenosine triphosphate formed and the amount of ferricyanide reduction assigned to the phosphorylating process should be observed, the linearity being a measure of the validity of the assumption and the slope of the line giving a measure of the stoichiometry of the phosphorylating reaction.

Fig. 1 shows that the experimentally determined points do indeed lie reasonably close to a line which represents the ratio of adenosine triphosphate to electron pairs as 2. (The points nearest the origin are, of course, those least precisely located since they represent values obtained by the subtraction of two very similar rates. However, their position consistently above the line may well mean that the assumed complete independence of the phosphorylating and uncoupled processes is actually only an

approximation of the truth.) This value of 2 agrees with the value obtained by Krogmann and Vennesland⁷ for their 'oxidative' photophosphorylation, a phenomenon which is probably fundamentally related in some manner not yet elucidated to the 'reductive' photophosphorylation described here. It would appear, therefore, that chloroplast phosphorylations occur either at two oxido-reduction levels, each stage involving a two-electron shift, or alternatively, at a single level with the transfer of a single electron. In any event the implied formation of two molecules of adenosine triphosphate for each triphosphopyridine nucleotide ion reduced would furnish more than enough adenosine triphosphate for the operation of the photosynthetic cycle proposed by Calvin and his associates⁸, whereas one molecule of adenosine triphosphate per reduced triphosphopyridine nucleotide molecule would be insufficient.

Fig. 1. Relationship between the amount of adenosine triphosphate formed and the amount of ferricyanide reduction which may be attributed to the phosphorylation-coupled electron-transfer system. In each event one micromole of potassium ferricyanide was reduced by illuminated pea chloroplasts in the presence of optimal concentrations of adenosine diphosphate, magnesium ions, hexokinase and glucose. The rates of reduction of ferricyanide and formation of adenosine triphosphate were varied by changing the phosphate concentration of the medium. The reduction to be attributed to the phosphorylating system (X) was calculated on the basis of the arbitrary assumption that the phosphorylating and non-phosphorylating systems were independent at high light intensities. Thus $X = A - B/A \times 10$ μmole, where A is the rate in the presence of phosphate and B is the rate in the absence of phosphate. Lines 1, 2 and 3 are the theoretical lines based on the above assumption with ratios of adenosine triphosphate to electron pairs equal to 1, 2 and 3 respectively.

Ramulosin, a $C_{10}H_{14}O_3$ Compound produced by the Fungus *Pestalotia ramulosa*

EARLY in 1959 we obtained through the courtesy of Dr. D. Brewer of the Atlantic Regional Laboratory a non-sporulating strain of *Pestalotia ramulosa* v. Beyma, an imperfect fungus belonging to the order Melanconiales. This strain was received as *Truncatella ramulosa* (v. Beyma) Steyaert, and is present in the Agricultural Research Service Culture Collection as NRRL 2826. When originally isolated by Brewer¹ from the tailing trough slime of a paper mill in New Brunswick, Canada, the organism formed spores typical of the species, but became asporogenous during subsequent transfers.

In the course of our culture work with this strain, we noticed copious formation of white crystals when the fungus was grown for 4-5 weeks at room temperature on malt extract agar (malt extract, 20 gm.; peptone, 1 gm.; d -glucose, 20 gm.; agar, 20 gm.; distilled water, 1,000 ml.). With the view of obtaining material for chemical investigation, we made a study of cultural conditions and found that in still culture as much as 370 mgm. of crystalline product accumulated on the surface of a nutrient solution (100 ml.) contained in an Erlenmeyer flask (300 ml.). A pure product (m.p. 121-122° C.), tentatively designated as ramulosin, was easily obtained by filtration, ether-acetone extraction of the dried mat, and recrystallization of the crude product from dilute alcohol. Elementary analyses and a Signer molecular weight determination showed the molecular formula to be $C_{10}H_{14}O_3$.

Optimum temperatures for growth and crystal formation have been determined to be about 20° C. and

15° C., respectively. Above 27° C., there is very little growth and no crystal formation. Still cultures in flasks at 15° C. showed visual evidence of crystal formation in about 26 days; the 370 mgm. yield we report was obtained in 93 days. *D*-glucose and *D*-glutamic acid appear to be the best carbon and nitrogen sources for crystal formation. No sporulation by *NRRL* 2826 has yet been observed by us. Two other strains of *Pestalotia ramulosa* which do sporulate did not produce crystals.

Chemical studies are in progress.

Effect of Tetracycline Antibiotics on the Proteolysis of Fish Muscle

DURING recent experiments on the storage of herring over a 21-day period in normal ice and in ices containing chlortetracycline and oxytetracycline, an attempt was made to correlate changes in the bacterial flora with some of the changes which occur in the muscle.

Observations on the lower volatile fatty acids have already been reported¹, when it was found that the antibiotics did not affect their rate of production. This work has now been extended to the free amino-acids, estimated by the method of Moore, Spackman and Stein².

The results obtained showed that the changes occurring in the amino-acids followed a regular pattern. Proline, methionine, threonine, alanine, glutamic acid, lysine, valine, isoleucine and leucine showed a gradual increase up to around the fourteenth day, followed by a decrease. Phenylalanine, tyrosine and serine showed little change, while histidine, arginine and possibly glycine decreased steadily throughout the period.

In the cases where the amino-acid content changed over the period, there was always a larger residue in the treated, compared with the untreated, fish, this difference being greater at 14 days than at 7 days. Bacterial counts were lower on the skins of treated compared to untreated fish.

There are three possible explanations for these observations: (1) the activity of the selected bacterial flora may be greater than that of the flora on the untreated fish; (2) the selected flora are primarily proteolytic (*Pseudomonas* spp. and *Achromobacter* spp.), and even if their overall activity is not increased relative to the untreated fish, accumulation of amino-acids may occur due to the reduction of other groups which utilize them; (3) autolysis in the muscle may continue independently of the bacterial flora, amino-acids thus formed being utilized by bacteria. Reduction in the number of bacteria due to the presence of the antibiotics then leads to an accumulation of the acids in the treated fish.

There is reason to believe that the flora selected during antibiotic treatment is less active biochemically, particularly in the presence of the anti-

biotics³⁻⁵. Many enzyme systems are also depressed by antibiotics⁶. Thus it is unlikely that increased proteolysis occurs during antibiotic treatment, and it is therefore possible that the increased accumulation of the amino-acids in the treated fish was due to reason (3), the acids being produced autolytically, and their rate of accumulation governed by their assimilation rather than their production by bacteria. Furthermore, the observation that the increase in the amino-acids occurred during the first fourteen days of storage—before the stabilization of the dominant bacterial flora—again indicates that during the critical early stages of spoilage, proteolysis proceeds independently of the bacterial enzymes.

These results will be reported in greater detail elsewhere.

Determination of Acid Phosphatase Activity in Cells of Prostatic Tumours

A SIMPLE technique by which cell material can be easily secured from prostatic tumours with the aid of transrectal aspiration biopsy has recently been described¹. The material thus obtained was shown to consist largely of plugs of epithelial cells with occasional admixture of blood. In the present work these tissue fragments were isolated for determination of their acid phosphatase activity.

The aspirate from the prostatic gland was suspended in 10 c.c. citrate buffer of pH 4.9 (ref. 2), containing 0.015 per cent 'Triton X-100' (ref. 3) and rendered hypertonic by addition of 2 per cent sodium chloride in order to minimize diffusion of the enzyme from the cells⁴. The large tissue fragments consisting of epithelial cells were sedimented by horizontal centrifugation for about 20 sec. at 500 r.p.m. In this series of experiments the sediment was washed twice more by re-suspension and centrifugation in the above-described medium. The isolated and washed cell material was finally suspended in 2 c.c. citrate buffer of pH 4.9 and stored in a refrigerator at 4° C. for 24 hr. The acid phosphatase activity of the cell-containing buffer solution was then estimated roughly by dropping 0.01 c.c. of the supernatant on to test paper specific for acid phosphatase, as previously described⁵. Taking as a guide the intensity of the coloured spot on the test paper, it was possible to select an appropriate incubation time (15–180 min.) for obtaining extinction for the final solution within the limits of the spectrophotometer used. In order to evaluate the enzymic activity quantitatively, the centrifuge tube containing the cell material in 2 c.c. citrate buffer of pH 4.9 was placed in a water-bath at 37° C. for 5 min. Substrate (0.2 c.c. of 1 per cent solution of disodium phenyl phosphate) was added to the tube. After a given time based on

* Enzymic activity expressed in μ gm. phenol liberated during 1 hr.

the activity estimated by the test paper method, the reaction was arrested by addition of 2 c.c. saturated sodium fluoride solution. The tube was centrifuged for 5 min. at 5,000 r.p.m.; the supernatant was then decanted into a test-tube and the amount of phenol therein determined according to the method of Stolbach *et al.*³, using a diazo reagent. The sedimented material was preserved for subsequent protein assay by the method of Lowry *et al.*⁶.

The acid phosphatase activity of cell material isolated from prostatic tumours—in most cases two parallel determinations were performed—is shown in Table 1. Also shown is the total protein content of the sedimented material following incubation, as well as the acid phosphatase activity per μ gm. of protein. It will be seen that the enzymic activity in cells isolated from prostatic carcinoma was lower than that in cells isolated from benign hyperplasia.

A more detailed report of the present work, including correlation of the acid phosphatase activity found in cells from prostatic tumours with the enzymic activity in circulating blood, will be published at a later date.

Diurnal Variation in Aldolase and Phosphatase Activity in the Cactus Plant

WHEREAS considerable information is available regarding the enzymatic mechanism of carbon dioxide fixation during acidification in succulents¹⁻³, very little seems to be known about the role of enzymes in the diurnal variation in acids and carbohydrate. If the 3-carbon atom acceptor of carbon dioxide is derived from starch or sugar by the Embden-Meyerhof-Parnas series of reactions, aldolase

may be expected to play an important part in the processes of acidification and de-acidification. We have studied the activity of aldolase in cactus tissue at different hours of the day and night, and have found a marked diurnal variation. Phosphatase activity was also found to undergo rhythmic alteration.

Nopalea dejecta used in the experiments was grown in the open, in garden soil. Aldolase activity was assayed by the method of Sibley and Lehninger⁴. The activity of the enzyme was expressed in mm.³ of fructose-1:6-diphosphate split in 30 min. at pH 8.6. Phosphatase activity, using pre-adjusted sodium pyrophosphate as substrate, was assayed by the method reported earlier⁵. A unit of this enzyme liberated 1 μ gm. orthophosphorus at 30° C. in 15 min. at pH 6.0. The specific activity of the enzymes was calculated in terms of mgm. dry weight.

The analytical data for aldolase, phosphatase, total acidity, total nitrogen (by the micro-Kjeldahl method) and protein (by the biuret reaction) obtained in a typical experiment are shown in Table 1.

Table 1. DIURNAL VARIATION IN *Nopalea dejecta*

Hours of collection of samples	Specific activity/mgm. dry weight		Acidity/gm. dry weight of tissue (ml. N/10 sodium hydroxide)	Total nitrogen/gm. dry weight of tissue (mgm.)	Protein/gm. dry weight of tissue (mgm.)
	Aldolase	Phosphatase			
8 a.m.	4.07	7.2	47.6	18.8	86
12 a.m.	3.32	10.3	11.7	19.6	101
4 p.m.	2.31	11.8	8.0	19.7	102
8 p.m.	3.00	10.6	12.6	18.4	82
12 p.m.	3.62	9.5	20.0	18.4	72
4 a.m.	4.96	9.5	23.8	17.9	68

The results show that aldolase specific activity was high at 8 a.m., and that there was a drop during the next 8 hr., the activity at 4 p.m., being the minimum. There was a subsequent progressive increase in the enzyme activity, the specific activity at 4 a.m. being the maximum during the 24-hr. period of observation. Phosphatase activity also showed a diurnal variation, but in the reverse direction and of a lower magnitude. The activity in the samples at 12 a.m. and 4 p.m. was higher than in the samples collected earlier in the morning and late at night. The titratable acidity was high in the morning and at night and was a minimum in the day-time, as was to be expected. Total nitrogen per mgm. dry weight did not alter significantly over the 24-hr. period. However, the protein content was found to alter, being distinctly higher in the samples collected at 12 a.m. and 4 p.m. It may also be pointed out that the diurnal alteration in the aldolase activity becomes even more prominent when the activity is expressed in terms of mgm. protein instead of mgm. dry weight. Assays carried out on mixed homogenates established that the diurnal variations in aldolase and phosphatase activity were real and not apparent.

The increased aldolase activity observed in the dark may be thought of as an adaptive response leading to increase in phosphoenolpyruvic acid, the acceptor of carbon dioxide during the acidification phase of crassulacean metabolism. As already reported⁵, the phosphatase of cactus homogenate is unspecific and acts also on fructose-1:6-diphosphate. It is likely that the increase in phosphatase activity in the day-time is related to increased synthesis of carbohydrate from organic acid, one step of which

series of reactions requires the hydrolytic split of a phosphate group of fructose-1:6-diphosphate.

Biochemical Chlorination in *Streptomyces aureofaciens*

THIS communication is concerned with the effect of chlorinated fatty acids on the formation of chlortetracycline. Experiments were carried out with shake cultures of *Streptomyces aureofaciens*, strain B-28 (ref. 1).

It has already been shown¹⁻³ that some strains of *Streptomyces aureofaciens* are able to utilize exhaustively the chloride content of an available medium for the synthesis of chlortetracycline. We have found that replacing the inorganic chloride of the medium by the organically bound chlorine of some chloro-fatty acids, the micro-organism was capable of using this different source of chlorine also for the synthesis of chlortetracycline. Quantitative differences could be detected in the rate of utilization of chlorine, depending on the structural position of the chlorine atom (Table 1). This type of chlorination was also substantially inhibited by bromide as well as 2,5-dimercapto-1,3,4-thiadiazole.

Table 1. UTILIZATION OF THE CHLORINE OF CHLORO-FATTY ACIDS FOR THE BIOSYNTHESIS OF CHLORTETRACYCLINE

Sodium chloride	($1.5 \times 10^{-3} M$)	Per cent
Chloroacetic acid	"	100.0
Dichloroacetic acid	"	84.5
Trichloroacetic acid	"	10.1
α -Chloropropionic acid	"	4.9
β -Chloropropionic acid	"	4.7
α,β -Dichloropropionic acid	"	67.3
α -Chlorobutyric acid	"	21.7
β -Chlorobutyric acid	"	8.3
γ -Chlorobutyric acid	"	53.9
α,β -Dichlorobutyric acid	"	70.3
	"	12.3

Considering the possibilities of chlorine utilization from chloro-fatty acids, three pathways may be suggested as shown in Fig. 1.

The first step in reaction 1 supposes a dechlorination of the chloro-fatty acid (enzymic or spontaneous) yielding inorganic chloride which would be utilized further in the usual way. The second reaction may be regarded as a 'transchlorination' process, that is, a transfer of chlorine from one substrate to another without mixing with inorganic chloride. In the case of the third reaction incorporation proceeds

Fig. 1. E_1 , E_2 and E_3 represent the enzymes or enzyme systems catalysing the different reaction patterns. R is substituted for a single or longer hydrocarbon chain, while R' has to be interpreted as a common hypothetical intermediate of the biosynthetic process leading to tetracyclines, which can be chlorinated to form chlortetracycline (CTC), otherwise in the absence of utilisable chlorine it participates in tetracycline production

without the cleavage of the original carbon-chlorine bond of the chloro-fatty acid.

Since our experimental results (to be published elsewhere) precluded the possibility of spontaneous chlorine decomposition, only an active enzymic dechlorination can be assumed for the first case. On the basis of our early investigations, occurrence of the third reaction type seems to be less probable. This conclusion is supported by the incorporation results obtained with the isomeric chloro-butyric acids, too; namely, in the case of an incorporation reaction proceeding without the cleavage of the carbon-chlorine linkage—particularly fragmentation of the fatty acid molecule is reasonably assumed by this process—the significant differences yielded with the chloro-butyric acids (Table 1) are scarcely interpretable. Considering the intramolecular structural arrangements of the variously substituted acids and the possibility of steric inhibition, results summarized in Table 1 can be well explained on the basis of reaction 1 or 2. More detailed results and discussion will be published shortly, elsewhere.

Hydroxyproline in Primary Cell Walls of Higher Plants

VARIOUS investigators have given evidence for the presence of protein in the cell walls of higher plants¹⁻⁴. We give evidence here for the occurrence of protein in the walls of sycamore (*Acer pseudoplatanus* L.), and bean (*Phaseolus vulgaris*). This protein contained hydroxyproline, and differed in this respect from the protein of the cell contents. Hydroxyproline has been found by Steward and Thompson⁵ to occur in the protein of tissue cultures of carrot and potato, and Pollard and Steward⁶ showed that the protein containing this imino-acid was stable in the growing cells and was not metabolized.

The plant tissues used in this work are listed in Table 1. The rotary shaker technique described by Nickell⁷ was used for growing the sycamore cell suspensions which were derived from callus tissue originating from explants of secondary cambial tissues taken from the tree in November 1958. Bean cell suspensions were derived from hypocotyl or seeds. Growth was measured by withdrawing samples from the cultures and determining the dry weight of cells per ml. of suspension over a period of 21 days.

Sycamore and bean cells were broken by shaking a thick suspension in water with glass beads (2 mm. in diameter) at approximately 50 c./sec. for 2 min. at 2° C. in a cell mill¹⁰. Microscopic examination showed

Table 1. ANHYDRO HYDROXYPROLINE CONTENT OF CELLS AND CELL FRACTIONS (PERCENTAGE DRY WEIGHT)

	Whole cells	Cell walls	Cell contents
Sycamore cell suspensions	0.51	1.28	< 0.1
<i>Phaseolus vulgaris</i> callus	0.425	2.7	—
Hypocotyl	0.86	0.88	—

that no intact cells were present after the procedure. The walls were isolated and washed 15 times with water by centrifugation (800*g* for 30 sec.). The cell contents were isolated by freezing and drying the supernatant from the cell-wall preparations.

The preparations were hydrolysed with 6 *N* hydrochloric acid in a sealed tube at 105° C. for 18 hr., and after evaporation under reduced pressure, the hydroxyproline was estimated by the method of Neumann and Logan¹¹. A quantitative amino-acid analysis was made by the method of Moore, Spackman and Stein¹². The results are shown in Tables 1 and 2.

Table 2. AMINO-ACID ANALYSIS OF SYCAMORE CELL WALL PREPARATIONS

	Gm. anhydro residues/100 gm protein	Residues/10 ⁶ gm. protein
Hydroxyproline	12.9	114
Aspartic	8.5	74
Threonine	3.8	38
Serine	9.4	108
Glutamic	8.2	64
Proline	4.5	46
Glycine	3.2	56
Alanine	3.8	50
Valine	6.2	63
Methionine	1.5	12
Isoleucine	3.8	38
Leucine	5.7	51
Tyrosine	5.1	31
Phenylalanine	4.4	30
Lysine	13.0	102
Histidine	3.4	25
Arginine	3.3	22
Hydroxyllysine	0.0	0

Of the total hydroxyproline of the cells, nearly all was found in wall hydrolysates, while only traces (< 0.1 per cent) appeared in hydrolysates of the cell contents. The percentage of hydroxyproline in the wall protein is similar to that of mammalian collagens¹³ but the amino-acid analysis shows no other similarities (Table 2). No amino-sugars have been detected.

Although the hydroxyproline content of the sycamore wall preparation varies slightly with different growth conditions, it remains the same when cells from the same culture are broken under various conditions. We have used cells suspended in 0.1 *M* triethylamine, in buffers at pH 2 (0.1 *M* glycine/hydrochloric acid and 0.1 *M* acetate), pH 10 (0.1 *M* borate), and in 40 per cent sucrose in which the cells were plasmolysed. These extreme conditions were chosen to neutralize acidic and basic groups respectively and to prevent adsorption of protein during cell breakage.

The percentage of wall in the cell may be calculated from the hydroxyproline content estimated for the whole cells and cell walls. For sycamore in the stationary phase of growth the figure obtained was high (40 per cent), but this agreed very well with that obtained by quantitative recovery of walls from a known weight of cells.

The primary nature of these walls is inferred not only because of their origin from rapidly dividing cells (the mean generation time during exponential growth was 48 hr.) but is also suggested by other work still in progress. This has shown (a) that the wall is about 1200-Å. thick when sectioned and examined with the electron microscope; (b) that parallel or fasciated microfibrils are not present; (c) that the walls contain pectin, hemicellulose and α -cellulose in proportions typical of cambial tissue.

The evidence suggests that protein containing hydroxyproline is an integral part of the wall of actively growing cells.

We wish to thank Miss B. Worboys for carrying out amino-acid analysis. One of us (D. T. A. L.) gratefully acknowledges the receipt of a grant from the Agricultural Research Council.

Note added in proof: We are pleased to note that D. K. Dougall and K. Shimbayashi (*Plant Physiol.*, 35, 396; 1960) detail essentially similar findings to our own.

PHYSIOLOGY

Kinetics of Muscular Contraction: the Approach to the Steady State

A DISTINCTIVE feature of muscular contraction is the dependence of the contractile force on the contraction velocity. For steady contractions, at a given length of the muscle, the interaction between force and motion is characterized by the well-known 'force-velocity' relation¹. In the present experiments this interaction has been characterized further by measuring the kinetics with which a steady contraction velocity is established following a step change in force.

The experiments were made with an apparatus which simultaneously measured both the motion of, and the force developed by, the sartorius muscle of the frog. The tibial end of the muscle was attached to a lever. Displacement of the muscle was measured by coupling the lever to an RCA 5734 transducer tube through a compliant spring. Force was recorded by measuring, with a second 5734 tube, the strain of the structure supporting the pelvic end of the muscle.

To minimize distortion of the displacement record by the inertia of the recording system, the lever was made as light as possible without sacrificing rigidity: the equivalent mass at the point of attachment of the muscle turned out to be approximately 170 mgm. The lever was loaded with a nearly inertia-less force, a compliant spring attached near the fulcrum and stretched by a weight. To dampen unavoidable high-frequency mechanical oscillation, viscous loading was also added: the lever was constrained to pull a length of wire (41 mgm.) through heavy oil. The loaded lever was prevented from stretching the muscle by a

Fig. 1. Response of frog sartorius muscle to a sudden change in force. Upper trace, displacement; lower trace, force; time marks, 10 msec.; standard length, 85 mm.; weight, 66 mgm.; temperature, 0° C. The muscle is initially at the standard length and the record is started after full tetanic force, P_0 , has developed. The vertical line defines t_0 . Afterload: (a) 0.84 P_0 , (b) 0.69 P_0 , (c) 0.55 P_0 , (d) 0.40 P_0 , (e) 0.26 P_0 , (f) 0.10 P_0 . In (g) the muscle is replaced by a spring of compliance 0.017 mm/gm. The afterloads in consecutive releases are the same as (a), (b), (c), (d) and (e), respectively.

stop; a second stop, which could be suddenly withdrawn, controlled release of the lever.

The muscle, in Ringer solution at a controlled temperature, was stimulated (0.1 msec. pulses, 30 c.p.s.) with a multielectrode assembly. After tetanic force (P_0) was fully developed, the stop on the lever was suddenly withdrawn. Recording started just prior to release of the lever: displacement and force were simultaneously displayed on the upper and lower traces of a double-beam oscilloscope.

A typical experiment showing the motion of the muscle when the load on the lever was suddenly reduced from P_0 to $P < P_0$, at 0° C., is shown in Fig. 1. The motion divides naturally into two phases, separated by the vertical line (which defines t_0). In the first phase, contraction is accompanied by a rapid fall in force. (This is the classical 'quick-release' experiment¹. The stress-strain relation in this phase characterizes the 'series elastic' element².) After the force of the muscle falls to the value of the load on the lever, there follows a second phase in which the displacement takes place at essentially constant force (isotonic). However, the contraction velocity does not reach the steady value $V(P)$ until at least 15 msec. after t_0 . For the force steps in a, b and c, the velocity is first greater than, and then less than, the final steady value. With greater force steps, d, e and f, the approach to the steady state is more discursive.

Is the delay in reaching a steady contraction velocity in the second phase attributable to the contractile element of the muscle or to the mass of the recording system? The latter possibility arises because the effective elasticity of the muscle and the mass of the lever interact to form an oscillating system. However, this inertial contribution to the displacement record can be evaluated because it is reflected as a corresponding transient in the force record. This is shown in g, where the muscle was replaced by a simple spring the elasticity of which approximates that of the 'series elastic' element. When the spring is stretched to a force of P_0 and the lever, with different afterloads, is released, oscillation in the displacement trace is exactly mirrored in the tension trace. The amplitude of this inertial transient increases with the magnitude of the tension step; the period is less than 4 msec.

In the experiments with muscle, since the force beyond t_0 is substantially constant in a, b and c, the velocity transients in these cases can be attributed entirely to the contractile element. The fact that the duration of these transients (> 15 msec.) is considerably greater than the period of the inertial transient (see g, and also the force traces of d, e and f) is in agreement with this conclusion. Of course, since P is constant there can be no change in the length of passive elastic elements in series with the muscle.

The same criterion applied to d indicates that the velocity transient in this case includes a just measurable inertial contribution. In e, and even more so in f (where the inertial contribution is just visible), the velocity transient is distorted by the inertia of the recording system.

The influence of temperature on the kinetics of the isotonic velocity transient is shown in Fig. 2. Releases from tetanic tension to the same afterload (one for which the transient is prominent) were made at 0°, 3.5°, 7.0° and then again at 0°. The duration of the velocity transient, Δ , estimated graphically, is obviously a function of temperature, which makes it extremely unlikely that the transient could have originated in the recording system. In fact, the temperature coefficient of Δ is nearly the same as that of V/P_0 , suggesting that both the duration of the transient and the characteristic speed are controlled by the same process.

It has often been supposed that the force-velocity relation for steady contractions, $V = V(P)$, can be applied to contractions in which P and V are not constant. Thus the motion of the contractile element has been calculated from the instantaneous tension, $P(t)$, by integration of the force-velocity relation¹:

$$\int V dt = \int V(P(t)) dt \quad (1)$$

This equation neglects the time required for the velocity of the contractile element to adjust itself to a change in force. Since the present experiments show that a measurable time, the magnitude of which depends on the change in force, is required for the steady velocity to become established, equation (1) cannot be expected to yield quantitative results. Careful analysis of the isometric myogram has led to the same conclusion⁴.

Fig. 2. Influence of temperature on the isotonic velocity transient. Upper trace, displacement; lower trace, force; time marks, 10 msec. Same muscle as Fig. 1. (a) 0°, (b) 3.5°, (c) 7.0° and then (d) 0°. Δ is a graphical estimate of the duration of the isotonic velocity transient.

The line defined by backward extrapolation of the steady contraction intersects the displacement trace very nearly at t_0 , which means that the time average of the velocity transient is approximately equal to the steady-state velocity. It is for this reason that the isotonic quick-release method of measuring series elasticity gives results similar to those found with the controlled-release method⁴.

The observed velocity of the muscle is the average of the velocities of the individual parallel fibres, weighted according to the fibre elasticity. If there were dispersion in either the force-velocity relation of the contractile elements or the stress-strain relation of the elastic elements, at t_0 the individual muscle fibres would begin to shorten at somewhat different velocities. However, the velocity differences would not persist because the difference between the displacement of the muscle and that of each fibre would be taken up in the fibre elastic element, changing the force therein, until the velocity of each fibre became the same. Since the change in muscle velocity resulting from this process will be considerably less than the range of fibre velocities at t_0 , it is unlikely that equilibration of fibre velocities could contribute appreciably to the very wide range of velocities in each of the isotonic transients described above. Also, the fact that the velocity transients were reproducible in more than 30 different preparations suggests that dispersion of fibre properties can be neglected. Apparently, the transients reflect directly the working of the contractile element; in this case, the kinetics provide a quantitative basis for evaluating models of the contractile process.

Disuse of a Central Synapse and Spontaneous Activity in the Optic Nerve

CURRENT theories of learning assume that transmission through a synapse is facilitated by repeated use of that synapse¹. Some support for this theory is provided by the occurrence of 'post-tetanic potentiation' at many synapses, although the duration of this effect, a few minutes at most, can scarcely reflect the long-lasting changes responsible for learning and similar phenomena. It has been argued that disuse of a synapse should produce the reverse effect, a decreased synaptic efficacy. The experiments of Eccles *et al.*² showed that after a few weeks disuse of the synapse between Ia afferents and motoneurons in the spinal cord there was almost complete absence of the post-synaptic response, but post-tetanic potentiation lasted for a much longer time than normally. In these experiments, disuse was obtained by severance of the afferent fibres, necessarily causing damage to the surviving parts of the neurones. These authors stressed the desirability of avoiding such damage in the study of disused synapses.

We have attempted to produce disuse in the dorsal nucleus of the lateral geniculate ganglion of cats, in the synapse between optic nerve fibres and lateral geniculate cells. In one series of experiments light was excluded from the eyes of adult cats either by keeping

them in a darkroom (4 cats kept for approximately 3, 10, 16, 17 months respectively) or by covering one eye with a special light-tight mask (1 cat, 2 months). In another series the visual receptor cells were selectively destroyed by oral administration of a drug, 1:5-di-(*p*-aminophenoxy)pentane dihydrochloride (M. and B. 9684)³; 5 cats have been examined at approximately 11 days, one month, 7 months, 7 months and 13 months respectively ('treated' cats).

The synapse has been studied by stimulating the optic nerve electrically and recording with a steel microelectrode the electrical field response in the lateral geniculate ganglion; the anaesthetic was allobarbitone ('Dial', Ciba). Briefly, we find the optic nerve normal in both groups by all our criteria—threshold, conduction velocity, excitability (both after single and repetitive stimulation). The post-synaptic response is also normal in the cats kept in darkness. It is only in the treated cats that there is any difference. Even here the response to a single stimulus is quite normal with regard to latency, amplitude and wave form; there is certainly no depression. However, during and following repetitive stimulation there is much less depression of the synapse than in normal cats.

Excitability of geniculate cells to orthodromic stimuli was measured in 2 of the treated cats using conditioning and test pulses in the usual way. In the normal cat there is a depression of the post-synaptic response maximal at about 20 msec. after a single response; at this time the response is reduced to about 32 per cent of normal (range 20–44 per cent)⁴. In the treated cats, apart from changes occurring within about 3 msec. (which were not examined in detail in these experiments) the excitability of the synapse did not fall below 70 and 80 per cent respectively.

Excitability was also tested in all cats by applying trains of stimuli. In the normal cat (Fig. 1a) geniculate cells will discharge only 3 or 4 times in response to volleys in the optic nerve at frequencies of about 250/sec.; cats kept in darkness behave similarly (Fig. 1b). On the other hand, in treated cats some geniculate cells can fire almost indefinitely at this rate and in general the postsynaptic response shows much less depression with successive afferent volleys (Fig. 1c and d).

There are also changes in the post-tetanic responsiveness of geniculate synapses. In the normal cat tetanic stimulation of the optic nerve at about 500/sec. for about 15 sec. is followed by a brief period of potentiation and then a period of depression, usually profound, lasting for hours^{5,6}. This depression, a very striking feature in the normal cat, is also obtained in cats kept in darkness but not at all in the treated cats, even after only 11 days blindness.

The retinas and lateral geniculate nuclei of several cats have been examined histologically. In cats kept in darkness both structures appear normal with Nissl staining. In the treated cats there was considerable destruction of visual receptor cells, but the bipolar and ganglion cells of the retina and the geniculate cells appear normal. We assume, therefore, that the drug has no direct action on any part of the visual system except the receptor cells. Now, although there is a spontaneous discharge in the retinal ganglion cells, this is dependent on the integrity of the visual receptor cells⁷. Hence in our treated cats the optic nerve must be relatively silent

Fig. 1. Recording from the lateral geniculate ganglion. Responses to a train of 6 or 8 stimuli applied to optic nerve. Stimulus strength about twice threshold in each case. Response to a single stimulus consists of a positive/negative wave (t_1) due to the large optic tract fibres, followed by a negative wave (r_1) due to the geniculate neurones. (+) Stimulus artefacts. Note that t_1 is only slightly affected during the train, whereas r_1 is greatly depressed in (a) (normal cat) and (b) (cat kept in darkness) and much less depressed in (c) and (d) (2 treated cats). Horizontal bars 10 msec. Negativity upwards.

and the electrophysiological changes we observe must be due to disuse of many of the lateral geniculate ganglion synapses.

Two important inferences can be made from these results. The first is that disuse in this synapse does not reduce synaptic efficacy; in fact the synapse shows an improved ability to transmit impulses. This observation is in agreement with those on the peripheral nervous system in which disuse causes hypersensitivity of the post-synaptic element, both to drugs and to nervous impulses⁸. This hypersensitivity can be produced not merely by denervation but also by section or inactivation of penultimate or even antepenultimate neurones. There is also evidence that similar effects can be obtained within the central nervous system⁹.

Because geniculate cells do not normally require much convergent activity to discharge them¹⁰ the single response might not appear very different even if the cells were hypersensitive. Furthermore, there is only a small 'subliminal fringe' of cells in the lateral geniculate ganglion¹¹. Hence a hypersensitivity would show itself only when the synapse was otherwise depressed, for example, during a tetanus and during the prolonged depression that follows a brief tetanus. Under such conditions the post-synaptic response remains large in the treated cats.

Although the disuse produced by Eccles and his colleagues may be a disuse complicated by damage, their finding that there is a parallel improvement in adjacent synapses which probably received increased use is free of this criticism and supports the assumption mentioned in the first sentence of this report. Experiments involving disuse of a synapse may not be helpful for theories of learning if the synapse involved has already been used. It might be more profitable to study synapses before they come into use, for example, in foetal material or very young animals.

The second inference is that since the geniculate synapses in cats kept in darkness do not show this change they cannot be disused and must therefore be receiving a continuous discharge from the retina. It is known that there is such a spontaneous discharge

in optic nerve fibres even after dark-adaptation for 1 hr. (apparently the longest period of observation)¹². Our results suggest that this discharge continues indefinitely in the dark. The spontaneous discharge of sensory receptors in the absence of obvious stimuli is well known, of course, and may be a necessary condition for a high degree of sensitivity.

Full details of these experiments will be published elsewhere. This work was aided by grants from the National Health and Medical Research Council of Australia, from the Ophthalmic Research Institute of Australia and from the Consolidated Medical Research Funds of the University of Sydney. Prophylactic Treatment of Post-traumatic Audiogenic Epilepsy

REACTIVITY of rats to a strong acoustic stimulus may be increased by the formation of artificial epileptogenic foci by local application of aluminium hydroxide (alumina-cream¹) in various regions of the brain, especially the cortical motor and acoustic area.

Foci treated with alumina-cream correspond morphologically and functionally to post-traumatic epileptogenic foci¹.

The possibility of preventing the onset of post-traumatic epilepsy by prophylactic administration of anti-epileptic drugs during the latency period, that is, between trauma and the appearance of the first seizure, has, as yet, neither been studied experimentally on animals nor statistically evaluated in clinical material.

In the present experiments an attempt has been made to influence the onset and the course of post-traumatic audiogenic epilepsy by prophylactic administration of phenyl-ethyl-barbiturates ('Dorminal', Spofa).

Experiments were performed on rats two months old, non-susceptible to an acoustic epileptogenic stimulus at 6-8 weeks of age. Since the non-susceptibility at this age does not exclude, according to our experience (at least in some of the genetic strains), the possibility of onset of audiogenic epilepsy at a

Table 1. NUMBER OF EPILEPTIC RATS, NUMBER OF RATS WITH CONVULSIVE SEIZURES AND AVERAGE NUMBER OF CONVULSIVE SEIZURES IN INDIVIDUAL GROUPS

Group	n	Epileptic rats		Rats with convulsive seizures		Average % of convulsive seizures
		number	%	number	%	
T	29	21	72.5	14	48.3	37.78

P	18	7	38.9	8	16.7	12.40
		1		2		8

Significance: $T \times O$ — $\chi^2 = 8.526$, $P = 0.05$
 $T \times P$ — $\chi^2 = 8.880$, $P = 0.05$
 $O \times P$ — $\chi^2 = 3.540$, $P = 0.05$
 $T \times P \times t$ — $t = 2.152$, $P = 0.05$

later age, a control group of rats was formed without trauma, the susceptibility of which to an acoustic epileptogenic stimulus was determined throughout the experiment and with which the experimental groups were compared.

The motor and acoustic area of the ipsilateral hemisphere was traumatized in 63 animals by micro-injection of 16 mm.³ alumina-cream with the aid of a stereotaxic apparatus. In 30 of these rats thus traumatized phenyl-ethyl-barbituric acid was administered for eight weeks in a dose 1.180 gm./kgm. body-weight *per os*. During the following six weeks this dose was gradually reduced to zero. Both groups of rats, traumatized and control, were then tested twice a week with a strong acoustic stimulus. The occurrence and symptomatology of the seizures was observed for a period of 150–160 days after trauma, or fifty-sixty days after termination of prophylactic treatment (that is, up to the age of 210–220 days). Twenty-nine traumatized rats, 18 traumatized rats with prophylactic anti-epileptic treatment and 31 control rats survived the experiment and were included in the final statistical evaluation.

Survey of results is given in Table 1 and Fig. 1.

From these it can be concluded that the number of epileptic rats in the group with prophylactic treat-

ment did not differ fundamentally from the control group. Prophylactic treatment thus reduces the occurrence of post-traumatic audiogenic epilepsy to the level of the control group and also reduced the occurrence of post-traumatic epilepsy with convulsive fits.

Rats in which audiogenic epilepsy occurred in spite of prophylactic treatment exhibited a significantly smaller number of convulsive seizures (see lower half of figure), that is, lighter forms of audiogenic epilepsy.

Rate of Passage of Inert Particles through the Alimentary Tract of the Cow

In studying the effect of physical factors on the rate of passage of food residues through the alimentary tract of animals, inert particles of known physical characteristics have been used (see, for example, refs. 1 and 2).

We have obtained new evidence on the effect of the specific gravity of an inert particle on its rate of passage through the alimentary tract of the cow. For this purpose rubber particles ranging in specific gravity from 1.02 to 1.21 and weighing 15 mgm. were used. Particles of each specific gravity and of different colours were placed (via a rumen fistula) in the reticulo-rumen and abomasum simultaneously and then recovered from the faeces. Particles from the reticulo-rumen gave a measure of the time particles were retained in the total gut, and those from the abomasum showed the retention in the hind gut; the difference between these two values represented the time of retention in the reticulo-rumen.

The time of retention of a particle in the reticulo-rumen was inversely proportional to its specific gravity, whereas the time of retention in the hind gut was directly proportional to the specific gravity of the particle. An example is shown in Table 1, giving the results of an experiment with four cows receiving approximately equal intakes of roughages. Mean times of retention for the four cows have been calculated by the method of Castle³.

Table 1

Specific gravity of particle	Mean time of retention (h) of particles in :		
	total alimentary tract (a)	hind gut (b)	reticulo-rumen (a-b)
1.02	102.2	29.0	73.2
1.06	81.0	30.5	51.1
1.12	73.4	37.6	35.8
1.21	70.5	51.7	27.8

Fig. 1. Above, white columns, percentage of epileptic rats in individual groups; black columns, percentage of rats with convulsive seizures; below, average percentage of convulsive seizures in relation to the total number of seizures in epileptic rats of individual groups.

T, group of rats with traumatic foci without prophylactic treatment; P, group of traumatized rats with prophylactic treatment; C, control group

King and Moore³ suggested that there is an optimum specific gravity of approximately 1.2 for the rate of passage of inert particles through the alimentary tract of the cow. Our results are similar, and show in addition that the time particles of equal weight are retained in the whole tract is a resultant of two complementary components each independently related to specific gravity. The relevance of this concept to the differential rates of passage of roughages and concentrate foods is being studied.

Renal Oxygen Tension

URINE oxygen tension is regularly lower than the oxygen tension of renal venous blood. When urine does not contain large amounts of reducing substances, for example, ascorbic acid, the urinary oxygen consumption is very low and cannot account for the low oxygen tension of fresh pelvic urine¹. It has been calculated that only insignificant oxygen tension gradient may exist across the tubule wall². The low urine oxygen tension therefore indicates that some segment of the tubule system has a lower oxygen tension than renal venous blood. Reeves *et al.*³ have suggested a low oxygen tension in the peritubular capillaries due to 'plasma skimming'³, and that urine oxygen tension is determined in the convoluted tubules. As the collecting ducts have been shown to be freely permeable to water and urea, however, an equilibration of the urine oxygen tension with medullary oxygen tension as well seems highly probable. Determination of the availability of oxygen to a platinum electrode introduced into the various zones of the dog kidney was therefore undertaken.

Healthy dogs, weighing 15–28 kgm., were anaesthetized by 'Nembutal', 25 mgm./kgm. body-weight, and one kidney exposed by a flank incision. No water was given on the day of experiment, and the dogs were accordingly in the antidiuretic state. Available oxygen was determined by a 0.4-mm. thick uncovered platinum electrode of 8-mm. length. A silver plate coated with silver chloride was used for anode. A constant potential of 0.6 V. was applied between the cathode and anode⁴. The platinum electrode was inserted vertically into the exposed kidney, generally causing negligible amounts of hemorrhage. The electrode was then moved stepwise into the renal parenchyma, 2–7 mm. each time, allowing time for stabilization at each point. After withdrawal of the electrode, indian ink was injected into the channel left by the electrode. The kidney was then removed and examined for exact localization of the electrode positions. Experiments were performed both during air and oxygen breathing. The fall-off of available oxygen produced by clamping the renal artery was examined with the electrode in various positions.

Available oxygen was regularly lower in the renal medulla than in the cortex. A stepwise decrease of

Fig. 1. Available oxygen in the various zones of the kidney. Electrode positions shown in schematic drawing (above). i.z., inner zone; o.z., outer zone

the electrode current was obtained in most experiments during stepwise introduction of the electrode from cortex to medulla. By pulling out the electrode in the same manner, the reverse picture was obtained (Fig. 1). Unfortunately no absolute values for oxygen tension are provided by the present technique. Clamping of the renal artery during oxygen breathing caused a very fast initial reduction of cortical available oxygen, describing an upward concave curve, while medullary available oxygen initially showed slow decrease and then fell off very rapidly, giving an upward convex curve. The difference is most readily explained from the oxyhaemoglobin dissociation curve by assuming an oxygen tension of the renal cortex of at least 80 mm. mercury and a medullary oxygen tension less than 60 mm. mercury during oxygen breathing.

The oxygen consumption is probably not higher in the medulla than in the cortex. The low medullary oxygen tension must therefore result from a relatively low medullary blood-flow, or from perfusion of the renal medulla by blood of low haematocrit. A decreasing oxygen tension towards the papilla might also result from counter-current diffusion of oxygen from the descending to the ascending limbs of vasa recta and the loops of Henle, as proposed by Levy⁵.

From the present findings the low urinary oxygen tension is readily explained by equilibration between the renal medulla and urine passing through the collecting ducts. It should be admitted, however, that the high oxygen tension of the renal cortex as determined polarographically does not necessarily imply a high oxygen tension in the peritubular capillaries. Blood of high haematocrit passing through hypothetical shunts in the cortex would presumably influence the polarographic reading to the same degree as would the cell-poor moiety passing through the peritubular capillaries.

Tissue Respiration and Transamination in Cold Stress

In the phylogenetic evolution of thermoregulation, under cold stress, liver and kidney tissues of poikilothermal toads show a marked increase in succinate and ascorbate oxidation to 105–150 per cent of that at 30° C.; in stenothermal birds, there is an increase of only 22–35 per cent, while in the homoiothermal rat there is a depression of 21–27 per cent. This indicates that in the rat the depression of respiration is greater in flavoprotein or preflavoprotein systems than in the cytochromes, while in the toad and bird the augmentation of respiration by cytochrome system is 1.2–1.3 times greater than in the flavoprotein or preflavoprotein systems¹. An attempt has been made in the present work to locate the nature of the evolution of oxidative enzymes in the preflavoprotein systems and also to indicate the nature of changes in oxygen consumption with amino-acid substrates and transamination in these systems.

regulation, flavoprotein and cytochrome systems were evolved earlier in the poikilotherms and in the stenothermal birds and the preflavoprotein systems were evolved much later in the homoiothermal mammals. The oxygen consumption with amino-acid substrate under cold stress increases in rat tissues and only in the liver of toad and bird, but the kidney tissues of the two latter species show a very marked depression in oxygen consumption. In cold stress, the transamination reaction is, however, increased in both liver and kidney of all three species examined. Cold stress is known to stimulate the secretion of thyroid hormone, and the possible role of this hormone on the preferential oxidation of amino-acid in the liver in contrast to kidney of toad and pigeon or the role of pyridoxine on amino-acid oxidation⁴ has not been determined in the present investigation. These results suggest that although transamination reactions have evolved quite early in the phylogenetic scale, amino-acid oxidation in the

Experiments were carried out on albino rats of either sex weighing 150–200 gm. and on pigeons and toads, thirty-two animals of each species being used. These animals were divided into two groups, one group being kept at 25° C. (control) and the other at 0° C. in a refrigerator for 2½ hr. (cold). The animals were killed, their liver and kidney collected, weighed and homogenized in isotonic cold potassium chloride solution. 0.4 ml. of 10 per cent homogenate was used in two Warburg flasks with pyruvate substrates for Krebs cycle oxidation², and in the other two with 0.5 ml. of 0.5 M sodium aspartate and 0.2 ml. of 0.5 M sodium α -ketoglutarate for the study of oxygen consumption³ and transamination reaction³. The gas phase was air and the oxygen measurement was made for 30 min. after an equilibrium period of 10 min. and, immediately after, transamination reaction was studied quantitatively by oxaloacetate measurement after decarboxylation to pyruvate⁴.

The results are shown in Table 1. The Krebs cycle oxidation system in the rat shows a depression of 15–19 per cent only at the lower temperature, and the depression is definitely in the preflavoprotein system rather than in the flavoprotein or in the postflavoprotein systems. A very slight augmentation of 11 per cent in toad and of 40 per cent in bird tissue indicates that the augmentation in cold stress lies at the flavoprotein and the postflavoprotein systems rather than in the preflavoprotein systems. This shows that in the phylogenetic evolution of thermo-

regulation, flavoprotein and cytochrome systems were evolved only to a small extent in the mammals.

I am grateful to Lieut.-Col. J. M. Lahiri, director of veterinary services and animal husbandry, West Bengal, and to Dr. K. C. Mukherjee, principal of this College, for their interest and advice.

Vitamin A Acid and Hypervitaminosis A

ALTHOUGH vitamin A acid plays no part in the visual cycle¹, it is active in the systemic functions of vitamin A in that it maintains normal growth and skin appearance^{2,3}. With Prof. R. A. Morton, we have found (unpublished work) that vitamin A acid also prevents the rise of ubiquinone concentration in rat liver, a characteristic effect of vitamin A deficiency⁴.

We have now compared the effectiveness of vitamin A acid with that of vitamin A (fed in the form of a high-potency fish oil) in producing hypervitaminosis A. Thus, two male rats weighing 95 and 105 gm. were fed daily 4 mgm. vitamin A acid (as the sodium salt).

Growth stopped and bleeding appeared around the eyes and nose after 4 days. One animal was killed after 10 days when apparently on the point of death; the other was killed in a similar condition after 17 days. The bones were very rarefied, and all long bones showed fractures.

Two other male rats weighing 63 gm. were fed 25,000 I.U. vitamin A ($\equiv 7.5$ mgm. alcohol) a day in the form of a high-potency fish oil (0.5 ml.). They grew slowly; the first fracture and signs of bleeding were noticed after 18 days. One of the animals died on the twenty-second day; the other was killed when on the point of death after 28 days. The bones showed signs of rarefaction which did not approach the severity of the resorption and rarefaction seen in the animals fed vitamin A acid. Only one fracture was found in each of the animals.

Vitamin A acid therefore produced the typical signs of hypervitaminosis A⁴ at a much lower dosage and in a much shorter time than did vitamin A itself (as the ester). These findings support the hypothesis⁵ that vitamin A acid is formed from vitamin A alcohol and is closer to the systemically active form of the vitamin. We suggest that feeding vitamin A acid is more effective in producing hypervitaminosis A because it by-passes the normal control on the supply of 'active vitamin A' to the tissues.

We wish to thank Prof. R. A. Morton for his advice, and Dr. O. Isler of F. Hoffmann-LaRoche and Co., Basle, for supplying the vitamin A acid.

HÆMATOLOGY

β -Globulin Variants in Two Species of Monkeys

VARIOUS β -globulin types have been demonstrated, using starch-gel electrophoresis, in several species of mammals, namely, man¹, cattle², sheep³, goat⁴ and horse⁵. The present communication reports the discovery of similar variations in two species of monkey, *Macaca mulatta* and *M. irus*. Variations in the monkey β -globulins were initially detected by paper electrophoresis using barbital buffer at pH 8.6. However, the β -globulins were much better resolved when starch-gel was used instead of paper.

Serum samples were obtained from 46 rhesus (*M. mulatta*) and 49 cynomolgus (*M. irus*) monkeys. Electrophoresis was carried out using the vertical starch-gel technique of Smithies⁶. The starch gels were prepared in borate buffer, pH 8.3, with hydrolysed starch (Connaught Medical Research Laboratories), and the serum samples subjected to electrophoresis at 20° C. for 16–18 hr. using a voltage gradient of 5–6 V./cm. After electrophoresis, the gel was sliced horizontally into two halves and stained with concentrated naphthalene black for $\frac{1}{2}$ min.

Fig. 1. Representative β -globulin phenotypes after vertical starch-gel electrophoresis of monkey sera. The sera were from left to right: 1, ADE'FG'; 2, A'B'D; 3, B'DF; 4, A'DE'F'; 5, ABC'D; 6, ABDE'. (Nos. 1–4 *mulatta* sera, and 5 and 6 *irus*)

Seven distinct β -globulin types were observed. The nomenclature used here is a modification of that of Ashton³. The β -globulins are designated by the letters A to G in order of decreasing mobility, so that A is nearest to the albumin and G to the point of origin. Three grades of stain intensity were observed. Faintly staining zones are denoted by the capital letter only; moderately staining zones by a single prime and intensely staining zones by 2 primes.

Fig. 1 shows representative patterns of the seven β -globulin variants A, B, C, D, E, F and G found in monkeys. In *M. mulatta* these are present in different combinations and proportions to give thirty-four phenotypes. Only fifteen phenotypes have been noted in *M. irus*. The variant of type E' and E'' is most commonly distributed in rhesus monkeys, occurring in 74 per cent (Table 1), while it is found in 31 per cent of cynomolgus monkeys. On the other hand, the type D' and D'' β -globulin is present in 33 per cent of the rhesus and 96 per cent of the cynomolgus monkeys. It is interesting to note that type A occurs widely in small concentration in both species. However, there is one instance of a phenotype in a rhesus monkey where three intensely staining zones can be demonstrated, one of which is the variant type A'. There is also a significant difference in the distribution

of the *F* types between the two species. The slowest β -globulin variant, *G* type, is very rare and only two rhesus monkeys in the sample possess this, and there is no case in the cynomolgus monkeys.

These observations indicate that the two species of monkeys differ appreciably in the frequency of the β -globulin phenotypes. If the β -globulins are divided into two groups, the fast-moving (*A* + *B* + *C*) and slow-moving (*D* + *E* + *F* + *G*) types, the difference between the two species is highly significant ($\chi^2_{(1)} = 10.3$; $P = 0.001$).

No attempt has been made so far to study the genetic control of the β -globulin types discovered in monkeys. In comparison with the β -globulin variants in other species of mammals, however, it seems likely that the genetic system controlling the β -globulins in monkeys may be fairly complex^{2,7}.

We are indebted to the Director, Commonwealth Serum Laboratories, Melbourne, for providing us with the samples of monkey serum and the Research Grants Committee of the University of Western Australia for financial assistance.

The 'Serial Thrombin Time' Method for measuring Fibrinolytic Activity in Plasma

AMONG the techniques described for the measurement of fibrinolytic activity, the elegance of the method of Wilhelm, Miles and Mackay¹ seems to have been unnoticed by many workers.

In this technique, a solution of fibrinogen is incubated with the fibrinolytic material, and from time to time samples are withdrawn and clotted with thrombin. As the fibrinogen is digested, its concentration in the reaction mixture falls, so that

the thrombin clotting time of the samples becomes progressively longer. The rate at which the thrombin times become lengthened depends on the rate of digestion of the fibrinogen, and hence on the activity of the fibrinogenolysin. It is convenient to express the thrombin times as ratios of the value at zero time; and the results may be summarized by the slope of the regression of this ratio against the duration of incubation of the reaction mixture, or by estimating the time taken to achieve a given ratio.

The method is attractive because of its simplicity, the rapidity with which results are available, and because individual readings of thrombin time may be taken at convenient (and irregular) intervals while other work is proceeding. Obviously, the more active the fibrinogenolysin, the more frequently should they be taken; but the appropriate reading-rate can soon be judged as the first few thrombin times are obtained.

Ingram, Norris and Tanner² pointed out that this technique could be readily applied to clinical samples of plasma. It is convenient to incubate in parallel samples of citrated plasma (say 2–3 ml.) from the patient and a normal control, starting as soon as possible after venepuncture. Immediately the experiment is set up, 0.1 ml. from each plasma is withdrawn and clotted by the addition of 0.2 ml. calcified human thrombin³ and the times recorded; unless the fibrinogen concentration is already much reduced in the patient's sample (when purified fibrinogen should be added to both samples to work the test) the ratio between patient's and control plasmas should be near unity. Thrombin times are then repeated on both plasmas at intervals of, say, 5, 10, 20, 30, . . . min. (according to the progress of the test), and ratios obtained between the paired readings; this eliminates error due to decay of activity in the thrombin reagent during the experiment.

The following experiment was carried out to study the relation between the increase in the thrombin time ratio and the digestion of fibrinogen in plasma. Fibrinolysin was prepared from normal human serum by streptokinase⁴ and three arbitrary dilutions were made. A portion of each was mixed with nine times its volume of a sample of normal plasma, and the mixture incubated at 37° C. Over a period of 5–6 hr., successive thrombin times were obtained, and a series of samples were also withdrawn for fibrinogen

Fig. 1. Ratio of weight of clot to initial reading plotted against ratio of thrombin clotting time to initial reading for three arbitrary dilutions of fibrinolysin. ●, 1/1; ×, 1/2.5; ○, 1/5

estimation by a clot-weight method⁵. For each experiment, the thrombin times and the clot-weights were expressed as ratios of their initial values, and one ratio plotted against the other for corresponding samples. The results of the three experiments are plotted in Fig. 1.

The graph shows a linear relation between proportionate loss of weight of clot and proportionate increase in thrombin clotting time, at least up to a doubling of the thrombin time. Above this level there is a suggestion that the thrombin time ratio rises more rapidly, perhaps due to the Kowalski effect⁶, which is thought to depend on a fibrinogen derivative inhibiting the reaction between thrombin and the remaining undigested fibrinogen; but on the whole the results confirm that, when applied to whole plasma, the Wilhelm, Miles and Mackay test provides a satisfactory indication of fibrinogenolysis.

RADIOBIOLOGY

Labelling of Inulin with Radioactive Iodine

INULIN is used in physiological experiments on renal function and for measuring the volume of extracellular water. Inulin consists of some thirty fructofuranose units linked through C(1) and C(2), corresponding with a molecular weight of about 5,000. The dispersion of molecular weight is thought to be such that nearly all molecules pass freely through capillary walls and the glomerular membrane; apparently inulin is not significantly metabolized during the experiments. Accurate determinations of inulin in biological fluids are required and these are usually colorimetric and involve subtraction of a 'blank' value, due to the presence of other carbohydrates. Radioactive labelling of the inulin could greatly facilitate such experiments. Ideally, labelling should cause the minimum change in the molecule. Carbon-14 could be introduced biosynthetically or tritium by exposure to the gas, but iodine-131 is more conveniently counted in many laboratories. We have experimented with the following reaction sequence on primary hydroxyl groups:

A satisfactory product was obtained, but the final labelling step, consisting of refluxing the tosyl inulin with sodium iodide in diethyl ketone, is neither a convenient nor an efficient method of labelling. An

alternative procedure is the introduction of an allyl ether group followed by addition of iodine at the double bond:

This was done as follows: inulin (5 gm.) in 50 ml. water was stirred under a reflux condenser, and allyl bromide (0.5 gm.) in 3.5 ml. methyl ethyl ketone was slowly added to produce a fine emulsion. The temperature was raised to 65–70°C. and 10.4 ml. N sodium hydroxide solution was added gradually during 30 min. After 6 hr. at this temperature, the mixture was cooled and neutralized with acetic acid. Electrolytes were removed by ion-exchange using a column of 'Biodeminrolite' and the solution was dried from the frozen state. The solid was extracted with hot ethanol, to remove an impurity absorbing ultraviolet light at 232 mμ, yielding allyl inulin (3.5 gm.). The intensity of absorption at 210 mμ, compared with that of allyl ethyl ether, indicated the presence of one allyl group per 14 fructose units. In aqueous solution, molecular iodine was found to react slowly with the double bond; in an iodine solution of approximately 0.0015 N, 100 mgm. allyl inulin combined with 2.5 mgm. iodine in 1½ hr. or 4.5 mgm. in 24 hr., the latter corresponding with one molecule of iodine per 35 fructose units. On oxidation with periodate, the allyl inulin was indistinguishable from the original inulin, 1.0 mole of periodate being consumed per fructose unit in each case. Thus the degree of substitution with allyl ether groups is very small.

The allyl inulin was labelled with iodine-131 using the iodine liberated by addition of 1 ml. of 0.05 N sulphuric acid to a mixture of potassium iodide (4 mgm. in 1 ml.), 75 μc. carrier-free and thiosulphate-free sodium iodide-131 (1 ml.) and potassium iodate (1 mgm. in 0.25 ml.). Allyl inulin solution (102 mgm. in 3 ml.) was added and the reaction was allowed to proceed at room temperature. After 3½ hr. sufficient sodium thiosulphate to react with excess iodine was added, and cations were exchanged for chloride by passage through a column of 'Amberlite IRA-400'. Some 25 per cent of the original radioactivity had combined with the inulin, but in a similar experiment this figure was raised to 48 per cent by allowing 24 hr. for reaction. Electrophoresis on paper of the labelled inulin solution in 0.05 M barbiturate at pH 8.6 and 4.5 V./cm. for an hour separated free iodide ions; these were located by an autoradiograph and counted by placing the portion of paper in a well-crystal scintillation counter. In preparations of the type described, about 2 per cent of the radioactivity of the labelled inulin solution was present in the form of free iodide; this percentage could probably be decreased by more efficient ion-exchange. Continuing the electrophoresis for 20 hr. followed by autoradiography showed the labelled inulin displaced towards the cathode by endosmotic flow of buffer solution. Hydrolysis of the labelled inulin in 0.5 per cent oxalic acid at 100°C. for 30 min. followed by electrophoresis of the hydrolysate in borate buffer of pH 10 on paper showed, on autoradiography, several labelled components probably corresponding with various substituted fructoses which have not yet been identified. Thus there seems no reason for doubting that the iodine is firmly attached to the almost unaltered inulin molecule.

In two preliminary experiments in rabbits, the labelled inulin was mixed with the original inulin and injected intravenously. The specific radioactivity of inulin appearing in the urine was measured. In early urine samples, the specific activity was lower and in later samples higher, than that of the injected material, suggesting that the labelled material was being excreted more slowly than the original inulin; the weighted average of the specific activities agreed well with the original value. In an experiment of this kind, molecular weight distribution is an important factor, and it is difficult to ensure that the chemical manipulations involved in labelling do not alter the molecular weight distribution, either by partial hydrolysis or by fractionation, so that the labelled inulin differs from the original inulin used for comparison.

In a subsequent experiment, the labelled inulin was mixed with the same batch of allyl inulin to ensure an identical molecular-weight distribution. Glomerular filtration-rate was measured in a rabbit for seven successive clearance periods, and the same rate was obtained for each period whether calculated from colorimetric determinations of inulin or from the radioactivity of the plasma and urine samples.

The reactions described can be applied to other polysaccharides, and dextran has been labelled in this way; labelled dextran fractions of known molecular weight distribution might be useful in permeability studies.

Uptake of Radioactive Magnesium in Liver Damage

BRANDT *et al.*¹ injected isotopic magnesium intravenously in the dog and found that kidney, heart and liver have a relatively high activity as compared with skeletal muscle; Rogers and Mahan² found a similar distribution in the rat following intraperitoneal administration.

Magnesium-28 has a half-life of 21.3 hr., emitting β - and γ -radiation. The specific activity is relatively low, nominal activity being about 50 μ c. per 100 mgm. of carrier. It is supplied as the chloride dissolved in hydrochloric acid by Brookhaven National Laboratories. This solution was neutralized to pH 6.5 with sodium hydroxide and diluted with water to contain 0.2 m.equiv./ml. of magnesium. Young male rats (120 ± 5 gm.) were given 0.5 ml. of the solution subcutaneously and killed 2 hr. later by decapitation. Whole heart (opened and rinsed with tap water), left kidney, skeletal muscle of the left abdominal wall, and a portion of the median lobe of the liver were taken and weighed. The samples of approximately 500 mgm. each were counted in a scintillation well. The results are reported as fractional activity: counts per min. per gram of wet tissue divided by the counts per min. of injected dose per gram of animal weight. Thus, if the isotope were evenly

Fig. 1. Fractional activity of liver (L), heart (H), kidney (K), and skeletal muscle (M) 2 hr. after subcutaneous injection of magnesium-28. Each horizontal line represents the mean value of tissues taken from 12 animals; the length of the vertical bar indicates two standard deviations

distributed and if none were excreted, the fractional activity of all tissues would be 1.0.

When control rats were killed 2 hr. after subcutaneous injection of the isotope, kidney and heart were found to be relatively active as compared with the moderately active liver and the relatively inactive muscle (Fig. 1). The activity of serum at this time was essentially the same as that of muscle.

In the course of studying the effect of carrier loading on the distribution of magnesium-28, it was noted that the liver of one of the animals appeared to be abnormal. The activity of a sample of this liver was markedly higher than any previously obtained. This observation led to the investigation of the distribution of magnesium-28 following the administration of hepatotoxic doses of carbon tetrachloride, turpentine and ricin.

Carbon tetrachloride and turpentine. Twelve unanesthetized rats were given 0.25 ml. of carbon tetrachloride subcutaneously. A second group of 12 were anesthetized with ether and given 0.05 ml. of turpentine intramuscularly. Twenty-four hr. later, 0.5 ml. of magnesium-28 solution was injected subcutaneously. The fractional activity of the liver 2 hr. after giving the isotope was significantly increased over control values in each instance (Fig. 1).

Ricin, a toxic extract of the castor bean, causes widespread tissue damage³. The dose of the preparation used, 0.1 mgm./kgm. subcutaneously, had been found to be lethal in 2-4 days. The 12 animals in this series were given the ricin 24 hr. before the administration of the isotope. When the animals were killed 2 hr. after injecting magnesium-28, the heart as well as the liver showed gross and microscopic damage. Whereas the fractional activity was again markedly increased in liver, the activity of the heart was not significantly different from control values (Fig. 1). This would suggest that increased

uptake of magnesium-28 is not a generalized reaction in tissue damage.

PATHOLOGY

Urinary Selenium and Dental Caries

Cadell and Cousins reported recently on the concentration of urinary selenium and prevalence of dental caries among two groups of children 5-14 years of age in New Zealand¹. From Table 1 of their article, all but two of the children in both groups had urinary selenium-levels in the range of 0.10-0.49 p.p.m. However, the mean values of urinary selenium given for the first and second group were 0.021 p.p.m. and 0.030 p.p.m. respectively. Obviously there is an error in the presentation of the data.

It is stated by Cadell and Cousins that: "The suggested direct relationship between urinary selenium concentrations and the prevalence of dental caries in American children is not substantiated by an investigation in New Zealand". In view of the data presented by them, this statement seems unwarranted and could lead to erroneous conclusions.

None of their subjects in both groups, having the same magnitude of dental caries, had values of urinary selenium in excess of 0.050 p.p.m. In our work, cited by Cadell and Cousins^{2,3}, more than half the children in the areas of high prevalence of caries had values of urinary selenium greater than 0.050 p.p.m. On the other hand, in the area with low prevalence of caries, the great majority of the children had values of less than 0.050 p.p.m. Admittedly, the possible dangers to health from the cumulative effects of daily ingestion of small amounts of selenium have been largely unexplored. In one case, however, the presence in the urine of a patient of selenium at a level of about 0.040 p.p.m. was considered to be suggestive of toxic amounts of ingestion⁴.

Apparently, Cadell and Cousins are under the impression that a direct relationship could exist between prevalence of caries and all levels of urinary selenium concentration. Such an assumption does not seem correct. It is like claiming that an inverse relationship exists between prevalence of caries and any amount of fluorides ingested, which, of course, is not the case. It is well known that small amounts of selenium are protective against dietary necrotic liver degeneration in rats and also prevent exudative diathesis in chicks^{5,6}. On the other hand, the ingestion of excessive amounts of selenium is harmful to animals⁷. If by further work it is shown that selenium is connected with caries, there certainly must be a threshold value of selenium intake, below which there is no influence on susceptibility to caries. Thus it may

well be that the ingestion of minute amounts of selenium, such as indicated by the mean urinary values shown by Cadell and Cousins, does not exert any influence, inhibitory or conducive, on the prevalence of caries.

The description presented by Cadell and Cousins regarding the methods used for assessing caries prevalence in their subjects is quite inadequate. Why did they combine prevalence of caries in primary and in permanent teeth? We have shown that the selenium content of primary teeth appears to be higher than that of the permanent teeth⁸. This becomes an important point in assessing prevalence of caries if the amount of selenium incorporated into the teeth during the period of formation of the crowns influences their future susceptibility to caries.

There is no doubt that further work is necessary for a better understanding of the possible relationship between selenium and caries. However, New Zealand does not appear to be suitable for such investigations since, according to Cadell and Cousins, that country has widespread areas deficient in selenium and also no known seleniferous areas exist there.

Histochemical Demonstration of Some Hydrolytic Enzymes in Atheromatous Aortas

IN connexion with other investigations made in this Department on the pathogenesis of atherosclerosis, our attention was directed to the histochemical changes in early atheromatous plaques. Barrows and Chow¹ suggested that a disturbance in the relative concentrations of enzymes within arterial tissue may result from arteriosclerosis. Relatively little is known, however, about the localization of enzymes in atheromatous aortas. Paterson *et al.*² demonstrated alkaline phosphatase in early atheromatous plaques, using Gomori's calcium-cobalt technique. They assumed that the activity was due to vascularization of the intima in early plaques.

We have made a histochemical study of the phosphatases³, esterase (with the naphthol AS method⁴), and leucyl aminopeptidase⁵, in atheromatous aortas. The samples were obtained fresh at autopsy and fixed overnight with cold, neutral 10 per cent formalin: sections were cut in a cryostat at 10 μ . The test for phosphatase was made at different pH's, and the highest activity was obtained at pH 5.8-6.2. This is in good accord with the results of Kirk and Praetorius⁶. This phosphatase was found by histochemical methods in atheromatous plaques only (Fig. 1) and could not be demonstrated in perfectly normal aortas. The activity was most intense at the margins of the plaques.

Fig. 1. Acid phosphatase activity in an early atheromatous plaque

Naphthol AS esterase seemed to appear in connexion with the foam cells and its localization corresponded well with the fat droplets visualized by lipid stains. The activity was most intense in the innermost layer of the intima and in the region of the membrana elastica interna. When the whole aorta was involved, distinct esterase activity could even be seen throughout the media (Fig. 2).

Fig. 2. Naphthol AS esterase activity in an atheromatous aorta

In aortas with occasional atheromas, moderate leucyl amino-peptidase activity was seen only in the earliest plaques, mainly in the thickened intima. In severely affected aortas many foci of activity were present even in the media.

It is known that phosphatase and naphthol AS esterase are most active in the aortas of those animal species which are least susceptible to experimental atherosclerosis^{7,8}. In this connexion the question arises whether the appearance of the two enzymes represents some defensive mechanism in the arterial tissue. Concerning the appearance of leucyl amino-peptidase, it is interesting that Monis *et al.*⁹ suggest that its activity is a biological property of proliferating connective tissue cells, and thus this enzyme, too, might be involved in this supposed defensive mechanism or repair mechanism¹⁰.

A more detailed investigation is in progress, the results of which will be published elsewhere.

Tissue Reaction to Polymethylmethacrylate in Rats and Guinea Pigs

IN 1890 Fraenkel¹ reported on the use of celluloid for the repair of a bony defect of the skull. Since then the increasing availability of plastics with widely differing physical properties has resulted in their use in many surgical procedures, particularly in orthopaedic surgery, where the implant is usually intended to remain in the patient for an indefinite period. So far as I am aware, no tumours have occurred in man in association with any of the plastics implanted. In animals, the occurrence of tumours in relation to an implant of a plastic material was first reported by Turner² in 1941. He found that fibrosarcomas developed in relation to 'Bakelite' disks implanted subcutaneously in Wistar rats. Since that time, many chemically different plastic materials have been shown to produce tumours when implanted subcutaneously in disk form in rats, mice³ and hamsters⁴. Originally it was thought that chemical agents were responsible for the development of these tumours⁵, but now the form and size of the implant are generally considered to be of greater significance.

In this Department the tissue reaction of the rat and guinea pig to disks of differing diameters of unplasticized polymethylmethacrylate implanted intramuscularly has been investigated. The polymethylmethacrylate sheet used was moulded from a polymer of methylmethacrylate which was prepared by the granular polymerization technique in which benzoyl peroxide was used as the initiator. The method of preparation was similar to that described by Wiley⁶.

Disks of three diameters, 18 mm., 12 mm. and 4 mm., and of a thickness 1.5 ± 0.5 mm., were implanted in the gluteal muscles of 153 female Chester Beatty strain rats and 86 female Hartley strain guinea pigs. The age of the rats at the time of implantation was three months, and of the guinea pigs six months. The animals were fed on a standard diet. In each animal the large disk was placed in the left, and the medium and small disk in the right, gluteal muscle mass. Spacing of the disks was such

that there was no difficulty in relating the tumours to the individual disks.

The implantations were completed two years ago. No rat survived for more than twenty-six months after operation, but forty-five of the guinea pigs are still alive. In the rats, thirty-four tumours have occurred in relation to the large- and sixteen to the medium-sized disk (these numbers may be slightly increased when the histology is completed). No tumours have been noted in relation to the small disk. The minimum latent period for the large disk—150 days—was considerably shorter than that for the medium disk—287 days. In only five rats were tumours associated with both the medium and the large disks.

Microscopic examination of the tumours revealed that the majority were fibrosarcomas, but a few rhabdomyosarcomas and osteosarcomas occurred. Tumour deposits, similar in type to those found around the disks, were noted in the lungs of nine rats and were considered to be metastatic deposits.

Tumours can thus be produced by the implantation of unplasticized polymethylmethacrylate in rats, the latent period being shortest with the large disk (18 mm.) which also gave the highest incidence of tumours. The absence of tumours associated with the small disks indicates that either there is a threshold size for disks for tumour formation, as suggested by Nothdurft⁶, or that the latent period for the small disk is greater than the survival-time of the rats in this experiment.

Microscopic examination up to eighteen months after implantation has shown no evidence of malignant changes in the fibrous tissue capsules which surrounded the disks in the guinea pigs. Palpation of the disks in the guinea pigs which are still alive—thirty months after implantation—does not reveal any abnormalities. This absence of malignant change in the guinea pigs could be due to a species difference, a greatly extended latent period, or to the disk being below the threshold size required for tumour formation in the guinea pig.

While it is recognized that there is most probably a species difference in response to implantation of plastic materials, the positive findings in rats suggest that there should be a long-term follow-up of patients in which the larger types of plastics implants have been used.

A fuller account of this work will be published elsewhere.

I wish to thank Dr. J. T. Scales, of the Department of Biomechanics, for his advice and encouragement, and Imperial Chemical Industries, Ltd., for technical advice. This work is being carried out with the aid of grants from the Nuffield Foundation and the Medical Research Council.

BIOLOGY

A Composite Response of Skin Homografts in the Rat

WORK on skin transplantation in rats has revealed a hitherto unreported phenomenon of interest to students of the fundamental biological reactions involved in the destruction of homografts.

A composite response—part survival, part necrosis, part modified necrosis—occurred in 27 of 49 grafts exchanged between members of a closely inbred colony of Wistar albino rats. This colony was started in 1939 from a single pair and it has been kept 'closed' since 1953. Prior to 1953 occasional additions from outside the colony were made. At no time was strict attention to the detail of brother-sister mating made.

Supracaricular grafts of full-thickness skin measuring at least $2\frac{1}{2}$ cm. $\times$ $1\frac{1}{2}$ cm. were removed from the dorsa of the rats. The animals were operated on in pairs, the grafts being exchanged between each member of the pair. Dressings consisting of 'Cellophane' and 'Elastoplast' were removed and first inspections made six days after the transplantation. Close daily observation of the grafts was made and has been continued for periods up to 170 days.

The results of the experiment are summarized in Table 1. Conventional total survival has occurred in three grafts for respective periods of 170, 158 and 148 days. The typical homograft response of total necrosis after 7–11 days of survival was seen in 15 cases, two showed a delayed necrotic process lasting twenty days and in two a prolonged destruction was not complete until the thirtieth day. There was no deviation from the conventional picture of total necrosis in forty-three control grafts, which were composed of two groups. In one group grafts were exchanged between members of a heterogeneous

Fig. 1. A large inbred strain homograft at the fourteenth day. A composite response with a geographical line of demarcation

Table 1

Fate of graft Type of grafts	Conventional response		Composite response				Total No. of grafts
	Total survival	Total necrosis	Survival and necrosis	Survival and modified necrosis	All modified necrosis	Modified and necrosis	
Inbred strain	3	19	11	7	6	3	49
Outbred strain	0	12	0	0	0	0	12
Inter-strain	0	31	0	0	0	0	31

completely outbred population, in the other group interstrain grafts were done, each pair consisting of one rat from the inbred strain and one rat from the outbred strain.

The interesting feature of a graft showing a composite response was that a circumscribed area of the graft, after surviving for 7-8 days, progressed through the whole gamut of the destruction of incompatible skin alongside and abruptly demarcated from another part of the graft which showed no pathological sign; the typical appearance of a composite response at 14 days is shown in Fig. 1; this graft was a 100 per cent 'take' at the six-day inspection with no remarkable characters. The surviving portion produced a good growth of hair, as Fig. 2 demonstrates.

An area of modified necrosis occurred in some cases with an area of unqualified survival, in others beside a part undergoing complete necrosis, and yet another group was observed in which the modified process affected the whole graft. At the usual time of homograft destruction such areas exhibited swelling, exudate and petechial hemorrhages which developed into scattered points of necrosis; the part survived, but was more indurated than a conventionally surviving part and hair growth was often more sparse and usually 7-10 days later in appearing.

Fig. 2. The same graft as in Fig. 1 at the forty-second day. The graft was rotated through 180° and the surviving part has a good pelt of reversed hairs; it has continued to survive for 86 days. The rejected part on the right half of the graft has contracted a little and shows some residual crusting.

Assessment of the survival of a homograft or part thereof was based on the observance of an unquestionable growth of hair with an unorthodox orientation, each graft having been rotated through 90° or 180° around a central vertical axis during transference from the donor to the recipient bed.

An explanation of these observations cannot be offered from the limited scope of the experiments reported at this stage, nor can it be obtained from the hypothesis of actively acquired immunity on which the structure of many arguments concerning the mechanisms of the reactions to homologous tissue seen in all animals above the lowest metazoan species have been based. However, further work on replantation experiments and on more closely inbred strains may indicate the specific factors involved.

I am indebted to Mr. W. J. Dempster for much helpful advice during the course of this work.

Occurrence of Bivalve Gastropods along the Coast-line of New South Wales

SINCE the descriptions of the animals and shells of two species of Australian bivalve gastropods, *Berthelinia typica* (Gatliff and Gabriel) and *Midorigai australis* Burn, were published earlier this year¹, I have had the opportunity to examine most of the beach drift material of these species in the collections of Mr. C. J. Gabriel, Melbourne, the National Museum of Victoria, Melbourne, and the Australian Museum, Sydney. This material revealed that both the species mentioned are to be found along the coast-line of New South Wales, and they are here recorded for the first time from that area.

(a) *Berthelinia typica* (Gatliff and Gabriel), one specimen (left valve only), No. C.63121 in the Australian Museum collection, collected in Gunnamatta Bay, Port Hacking, N.S.W., by J. Laseron. This valve is typical of small *B. typica* valves in that it is not as sharply pointed posteriorly as my figures indicate (ref. 1, Figs. 1-2).

(b) *Midorigai australis* Burn, one specimen (left valve only), No. C.63120 in the Australian Museum collection, collected at Fairlight, North Harbour, Sydney Harbour, N.S.W., by M. Burrows and J. Laseron. This minute valve, 0.8 mm. long and 0.5 mm. high, is very similar to small specimens in the paratype series, although the upper anterior margin is not so high, nor is the upper posterior margin so angled. The protoconch is typically discoidal, and this distinguishes the valve from *Berthelinia*, where the protoconch is described as helicoidal.

Both these species belong to the molluscan order Sacoglossa, family Berthelinidae.

Careful searching of the green alga *Caulerpa* at various localities in New South Wales during the 1960/61 summer period will, I hope, reveal the living animals of both species, possibly along with other sacoglossans which feed on the same food.

Northern Limits of *Elminius modestus* in Britain

RECENTLY, Powell¹ reported the occurrence of two specimens of the immigrant barnacle *Elminius modestus* at Keppel Point, Isle of Cumbrae, where the species was reported some four years previously by Connell². This is only the second record of the species north of Loch Ryan, though it has been present in the Loch and farther south for some time³. Its presence in very small numbers at scattered points on the south-west coast of Scotland is to be expected, since it has now colonized shores on all sides of the Irish Sea and has been found beyond the North Channel in Loch Foyle⁴.

In March 1960 *Elminius* was found sparsely scattered over a wide area in the Gare Loch, Dumbartonshire, north of the Clyde, though no specimens were found in the Clyde estuary itself, nor in the neighbouring Lochs Long and Fyne, nor farther north in Loch Linnhe. It may be significant that there is a naval dockyard in the Gare Loch and shipbreaking yards, as in Loch Ryan. The individuals found in the

Gare Loch were mostly small ones which had evidently settled late in 1959, and, though they were seldom seen sufficiently close together to be able to breed, were nevertheless found in numbers at all the piers, jetties and breakwaters which were examined (Fig. 1), the greatest densities occurring towards the head of the Loch. Hydrographic conditions in such a deep and long body of water would be ideal for retaining larvae liberated by introduced barnacles.

On the east coast, the Humber has marked the limit of *Elminius modestus* for some years². However, in March 1960 considerable numbers were found to have settled between the Tees and the Humber. On the piers at Saltburn the density reached 20 individuals per square metre. Smaller numbers were found at Scarborough and Bridlington.

The northward spread of the species, both on the west and the east coast, following a period of some five years in which the species had shown little advance, is probably to be ascribed to an increase in the fecundity of the species caused by the exceptionally warm and prolonged summer of 1959.

Fruit-Setting of Apples using Gibberellic Acid

ATTEMPTS in the past to produce parthenocarpic development of pome fruits with growth substances have had only very limited success^{1,2}. Because of a greater natural tendency towards parthenocarp, experiments with pears have been much more successful than with apples. Luckwill³, however, recently reported that gibberellic acid sprays caused the initial development of seedless fruitlets on several apple varieties, although with only one, Miller's Seedling, did treated parthenocarpic fruits reach maturity. In experiments at this Division during the 1959-60 season, gibberellic acid, applied as a 1 per cent lanolin paste, has produced mature seedless fruits on four apple varieties—Sturmer, Cox's Orange and two cider varieties, Strawberry Norman and Red Jersey.

Before treatment, petals, stamens and style of flowers on small branches were removed at the pink stage with a sharp blade. Except with Red Jersey at least 80 flowers per treatment were used. Paste was then smeared on the cut surface and around the inside of each receptacle. On Sturmer, additions of 2,4-dichlorophenoxyacetic acid (0.125 per cent) alone or together with kinetin (0.025 per cent) to the gibberellic acid did not appear to enhance the effect of the latter. A single spray of 400 p.p.m. gibberellic acid was as effective as the grease treatment on Strawberry Norman, the only variety on which this method of application was tried.

Subsequent swelling of treated receptacles was rapid and comparable with that of normal seeded fruits. At an early stage the majority of treated flowers appeared to have set. However, many of these fruitlets developed only partially and a heavy drop occurred 5-7 weeks after treatment. The remaining

Fig. 1

fruits on three of the varieties, Sturmer, Red Jersey and Strawberry Norman (some 8, 40 and 28 per cent respectively of treated flowers), continued growth and attained a final size at harvest only slightly smaller than the average size of normal seeded fruits from the experimental trees. Treated fruits maturing on Cox's Orange (12 per cent of flowers treated) were only half the size of seeded fruits. With normal pollination, fruit was harvested from 10–15 per cent of flowers on the above varieties. No fruit set on control flowers of any of the varieties on which the petals, stamens, and style had been removed similarly.

In colour development, time of ripening and general quality, parthenocarpic fruits produced by the gibberellic acid treatments were similar to normal fruits. Treated fruits of Red Jersey were noticeably more elongated than normal fruits; but this tendency was only slightly apparent on other varieties. A proportion of the treated fruits of all varieties developed some unevenness, being lopsided or otherwise asymmetric. A characteristic puckering around the calyx occurred particularly on Red Jersey and Strawberry Norman. The gross morphology of the seedless fruits was similar to that of normal fruits. In the absence of seed development, walls of the carpel chambers were sometimes pressed closely together. Undeveloped ovules remained as small brown rudiments no more than 1 mm. long. Treated branches developed flower buds normally during the season.

Although gibberellic acid failed to show any effect during *in vitro* studies of the growth requirements of apple tissue⁴, the present results suggest that in normal development of apple fruits the naturally occurring gibberellins may perform a specific role. It is of interest that a similar positive effect of gibberellic acid on fruit set of *Rosa* has been recorded recently⁵. Success of the direct applications of gibberellic acid suggests that such treatments might have considerable practical value in overcoming fertilization problems in apple crops.

Direct Transmission of a Growth-promoting Substance from Strawberry to Pea

RECENT papers by Guttridge^{1,2} have provided evidence that photo-periodically controlled growth responses in the strawberry may be regulated by a hormone, produced in long days, which promotes vegetative growth and inhibits flower initiation; and that gibberellic acid may simulate the action of this hormone in plants growing under short-day conditions³. Brian and Hemming⁴ found that plants of *Pisum sativum* var. Meteor will respond by increased length of internode to as little as 0.01 μ gm. of gibberellic acid.

Fig. 1. Effect of grafting *Pisum sativum* var. Meteor on to petioles of strawberries previously treated with gibberellic acid. Control a peas retained in pots; control b peas treated for grafting

In view of the small quantity of gibberellic acid required to give a measurable response in the pea, an attempt was made to obtain direct transfer of the growth-promoting hormone from the strawberry to Meteor pea plants by making a tongue approach graft between the blanched epicotyl of a pea and a strawberry petiole. After grafting, the roots of the pea plant were placed in a 3 in. $\times$ 1 in. sample tube containing Long Ashton mineral nutrient solution⁵. Controls were set up in the same way with their epicotyls cut as for grafting. No graft union was ever formed, and after the sixth internode had expanded the peas were harvested and the length of each internode was recorded.

Fig. 1 shows the mean length attained by successive internodes of Meteor peas grafted on to plants of the strawberry variety Climax, which had been sprayed seven days previously with a solution containing 100, 50 or 25 p.p.m. of gibberellic acid. Fifteen plants were used for each treatment and one pea plant was grafted to each. Also shown is the response of peas grafted on to untreated strawberry plants. Two control series of peas were used; in one, the plants were removed from the pots and treated as for grafting; in the other, they were left to grow undisturbed in their pots.

The internodes of all grafted peas were longer than either the ungrafted controls or the controls which were grown on in their pots. Pretreatment of the strawberry plants with high (50 or 100 p.p.m.) levels of gibberellic acid resulted in additional elongation of the internodes of peas grafted to them.

Brian and Hemming have shown that applications of gibberellic acid have less effect on tall than on dwarf varieties of peas⁴. To determine whether peas responded to grafting in a similar way, 15 plants of each of six different varieties of peas were grafted on to large plants of the strawberry variety Redgauntlet growing in the glasshouse. To confirm the response of these pea varieties to gibberellic acid, 10 plants of each, growing in pots, were either left untreated or treated with gibberellic acid at 0.02 $\mu\text{gm./plant}$ or 0.32 $\mu\text{gm./plant}$.

Table 1. RESPONSE OF DIFFERENT VARIETIES OF *Pisum sativum* TO APPLICATIONS OF GIBBERELIC ACID: AND TO GRAFTING ON TO PETIOLES OF STRAWBERRY

Variety	Growth habit	Percentage increase on respective controls:		
		Grafted	Gibberellic acid at 0.02 $\mu\text{gm.}$	Gibberellic acid at 0.32 $\mu\text{gm.}$
Meteor	Dwarf	157	155	210
Progress No. 9	Dwarf	149	147	188
Little Marvel	Dwarf	127	140	185
Greenland	Intermediate	137	120	156
Gladstone	Tall	122	116	105
Thomas Laxton	Tall	124	123	115

Table 1 gives the lengths of the first internode to elongate after treatment, expressed as a percentage of the length of the corresponding internode in the control series of each treatment.

The response to grafting of each variety of pea used, with the possible exception of Little Marvel, was similar to its response to an application of 0.02 $\mu\text{gm.}$ gibberellic acid.

The strawberry is a plant in which gibberellic acid can serve as a substitute for the dormancy-breaking effect of winter chilling. After chilling, plants grow very strongly when brought into conditions favourable for growth, in contrast to unchilled plants in which the petioles remain short and prostrate. Fig. 2 shows the mean lengths attained by successive

Fig. 2. Effect of grafting *Pisum sativum* var. Meteor into petioles of strawberries growing in the glasshouse. —, Following winter chilling; ---, without previous chilling

internodes of peas, variety Meteor, grafted on to the petioles of chilled and unchilled plants of the strawberry Redgauntlet, growing in a glasshouse. Each set is the mean of ten plants, each of which was grafted to a different strawberry plant.

Grafting peas to chilled strawberry plants resulted in a greater response in internode-length than did grafting to unchilled strawberries.

The experiments show: that Meteor peas respond by increased internode-length when grafted on to petioles of strawberry leaves; that the response is increased when the strawberries have been previously treated with gibberellic acid; that the responses of different varieties of peas to grafting are similar to their responses to treatment with gibberellic acid; and that chilled strawberry plants, in which there may be endogenous gibberellins, promote a greater response than do unchilled plants in which endogenous gibberellins may be low.

Further work is now in progress with the intention of publishing a fuller account of the technique. It is hoped that the method may provide a rapid quantitative technique for the estimation of gibberellic acid-like substances in plants without the necessity either to make an extract or to destroy any part of the plant sampled.

Intra-ovarian Pollination in *Papaver rhoeas* L.

In many crosses plant-breeders are confronted with one or more of the following problems: (1) the pollen grains may fail to germinate on a foreign stigma; (2) if they germinate, the pollen tubes may remain short and burst during their passage; (3) even if the tubes grow successfully, their progress may be so slow that the ovary becomes abscised before they reach the ovules.

Grafting the style on the ovary, shortening it to a suitable length, and removing the middle portion and joining the upper and lower parts of the style together have been tried from time to time to overcome some of these barriers¹.

Intra-ovarian pollination is yet another device. Dahlgren¹ was able to bring about fertilization in the ovules of *Codonopsis ovata* by this method. The experiments of Cappelletti² on *Digitalis purpurea*, and of Bosio³ on *Helleborus foetidus*, *H. viridis*, *Paeonia anomala*, *P. officinale* and *P. peregrina* also indicated the possibilities of this technique. In *Paeonia*, Bosio obtained viable seeds. This communication describes the results of some intra-ovarian pollinations conducted on plants of *Papaver rhoeas*.

The following steps are involved: (1) determination of the time of anthesis, dehiscence of anthers and of pollination; (2) emasculation and bagging of flower buds; (3) collection of pollen grains; (4) determination of the conditions and medium for optimum germination of pollen; (5) injection of a suspension of pollen grains into the ovary.

Fig. 1. Ovary injected with pollen suspension. The petals and stamens have been removed to show the hole made by the needle. ($\times 3/5$)

Figs. 2 and 3. Ovaries six and nine days after injection. ($\times 3/5$)

Fig. 4. Nine-day-old ovary cut vertically to show maturing seeds. (c. $\times 3/5$)

The pollen suspension was prepared in 2 c.c. of sterile, double-distilled water with 0.01 per cent boric acid, each drop containing nearly 100 pollen grains. An all-glass 'Insuline' syringe (capacity 1 c.c., graduated to 40 units) was used. Before injection the surface of the ovary was wiped with cotton soaked in rectified spirit. A hole was made on one side of the ovary to allow the air to escape, and another on the opposite side through which the pollen suspension was injected until the ovarian cavity was filled with it. The cavity was considered full when the fluid started oozing out from the first prick. Care was taken to shake the syringe before each injection, so that the pollen grains were uniformly distributed. After the operation the holes were sealed with petroleum jelly.

When the calyx, corolla and androecium were all removed the ovaries became pale yellow; if only the stamens were excised leaving the petals and sepals intact, the development was better, and hence this procedure was always followed after the first few trials.

The growth of ovaries injected with a pollen suspension in sterile double-distilled water matched fairly well with naturally pollinated ovaries. Concomitant with the growth of the ovary, the ovules also developed and the embryos grew faster than in Nature. The cotyledons differentiated within fourteen days after anthesis; by the third week the plumule and root tip were well differentiated; and month-old seeds had fully developed embryos.

The experimentally obtained seeds were viable and behaved just like those obtained from naturally pollinated ovaries. When soaked in tap water for 24 hr. and cultured on modified White's medium there was 100 per cent germination, and healthy seedlings were obtained. Counts from the squashed root tips of seedlings from both sets showed 24 chromosomes.

The injected ovaries showed a 40-70 per cent seed set (Figs. 1-4). Seeds also matured in ovaries injected with an aqueous suspension of pollen without boric acid, but were fewer in number.

The technique of intra-ovarian pollination may prove useful in overcoming incompatibility between two plant parents. Further work is in progress.

I am grateful to Prof. P. Maheshwari for guidance and encouragement. Thanks are also due to Drs. S. Narayanaswami and N. S. Ranga Swamy for their help and valuable suggestions.

MICROBIOLOGY

Misinterpretation of an Agar-Gel Precipitation Pattern

THERE are certain recognized pitfalls in the reading of precipitation patterns in agar-gel immunodiffusion plates¹⁻³. Occasionally, a new pitfall is inadvertently introduced by the design of well-pattern employed in a particular plate. Such is the case in the plate depicted in Fig. 2 of the communication in *Nature* of Pepys *et al.*⁴.

I reproduce herewith (Fig. 1) the relevant part of the well-pattern employed by Pepys *et al.*, using their numerical notation. In their original paper the two large wells each received the same serum. In well 1 had been placed *Trichophyton rubrum* cell-sap; in well 3, *Aspergillus fumigatus* cell-sap.

A two-armed band of precipitate, produced by this antigen-antiserum placement, ran continuously between the two antigen wells on one side and the two antiserum wells on the other. One arm extended beyond well 3, the other terminated opposite well 1. The authors assumed that each arm had arisen as an independent band, arms 1 and 3 afterwards fusing in the so-called "reaction of identity". From this they concluded that *T. rubrum* and *A. fumigatus* "possess common antigenic determinants".

What they had failed to take into account was the possibility of antigen from well 3 reacting with antibody from the far antiserum well, as well as from the near, thus being the sole antigen responsible for the entire precipitation band. This seemed to me the more likely explanation, especially in view of the manner in which arm 1 terminated on a level with and failed to extend beyond well 1.

Fig. 1

Fig. 2

Fig. 1. Large wells: rabbit anti-ovalbumin serum; well 3: ovalbumin 1:1,000; well 1: saline

Fig. 2. Large wells: rabbit anti-ovalbumin serum; well 3: ovalbumin 1:1,000; well 1: ovalbumin 1:100,000

To test this view, a plate was set up in which a rabbit antiserum to ovalbumin was placed in both large wells and an ovalbumin solution placed in well 3, while well 1 received only saline. The precipitation band produced (Fig. 1) was identical with that of Pepys *et al.*

To determine the effect of fractional concentrations of antigen in well 1 on arm 1 of the band, plates were set up in which well 1 received tenfold and hundredfold dilutions of the ovalbumin solution in well 3. Fig. 2 shows the perceptible deflexion and extension even a hundredfold weaker antigen produces on the free end of arm 1 of the band. From this it appears to me that, in the original plate of Pepys *et al.*⁴, the *T. rubrum* cell-sap could not have contained as much as 1 per cent of an antigen immunologically related to the antigen in the *A. fumigatus* cell-sap responsible for the precipitation band. The photographs are by Douglas F. Lawson from plates by Anne Temple.

J. G. FEINBERG

Bencard Allergy Research Unit,
Beecham Research Laboratories, Ltd.,
Betchworth, Surrey.

¹ Feinberg, J. G., *Int. Arch. Allergy*, **11**, 129 (1957).

² Feinberg, J. G., *Biochem. J.*, **65**, 1P (1957).

³ Feinberg, J. G., and Grayson, Hazel, *Int. Arch. Allergy*, **16**, 1 (1960).

⁴ Pepys, J., Riddell, R. W., and Clayton, Y. M., *Nature*, **184**, 1328 (1959).

As pointed out by Dr. J. G. Feinberg, the pattern of wells in the agar-gel plate (Fig. 2) of our communication in *Nature* of October 24, 1959¹, lends itself to misinterpretation. However, the presence of common antigenic determinants in extracts of *T. rubrum* and *A. fumigatus*, which figure in the plate, was demonstrated by inhibition tests. These, together with all the other tests in our communication, were performed on conventional agar-gel patterns (Fig. 1, ref. 1). Nine sera were tested for their capacity to precipitate against these two fungal extracts, after the addition of each of them to the serum. The addition of *A. fumigatus* extract resulted on one hand in complete inhibition of its own precipitation lines with six and partial inhibition with the remaining three sera, and on the other hand in complete inhibition of the *T. rubrum* extract precipitation lines with seven and partial inhibition with a further one serum. The addition of *T. rubrum* extract resulted in complete inhibition of the precipitation lines of the *A. fumigatus* extract with six sera, and of its own precipitation lines with all nine sera.

The problem of related antigenic determinants in extracts which may not produce identical patterns, or may not in some cases produce any precipitation at all, but may nevertheless effectively inhibit the precipitation lines of extracts from sources of known or as yet unknown relationship, has been encountered by us in work on mycobacterial extracts² and on the *Aspergillus* genus³. It seems reasonable to assume some antigenic relationship from these findings, whether or not reactions of identity are produced by these extracts in agar-gel tests with appropriate patterns.

Bi-nucleate and Tri-nucleate Conidia in *Colletotrichum gossypii* South

AN isolate of *Colletotrichum gossypii* which was kindly sent from Arkansas by Dr. N. D. Fulton (his No. 6110) produces spores in culture showing great variability in size and shape. This state of affairs has been well known in the genus since the early reports of Alwood¹ and Burger².

Cytological work using an acid giemsa technique has shown that in this isolate, under conditions of culture *in vitro*, the variable size of the conidia is apparently associated with a variable number of nuclei per conidium. This is normally one, but may be two or three or rarely up to five per spore. The conidia are abstricted terminally on conidiophores, which in this case are no more than mycelial branches of specialized function, and in slide-culture preparations remain in clusters around the parent conidiophore. Often, but not always, pleurinucleate spores occur together in these clusters.

No evidence has been found for the migration of more than a single nucleus into the conidium before abstriction. What appears to happen is that, after abstriction, the spore may continue to grow to a limited extent, and that in this case the increase in cytoplasmic volume is accompanied by nuclear division. In some cases the bulbous distal end of the larger spores suggests that a setback has been followed by a fresh burst of growth³. The cultures were examined after four days growth at 25°C. in the dark. None of the spores was apparently germinating, and the pleurinucleate condition is thought to arise in the development of the spores before hardening of the wall, rather than being associated with spore germination.

The fungus was handled before fixation as a Duncan slide culture or by Dade's method⁴. The agar was removed and the fungus fixed and stained *in situ* on the cover-glass on to which it had grown. Fixation was in Newcomer's fixative⁵ over-night. After passing through 70, 50 and 30 per cent alcohol the

Fig. 1. Conidia of *Colletotrichum gossypii* South on mycelium growing on glass from glucose yeast agar, stained acid-giemsa. Photomicrograph using a $\times 45$, 3.75 mm., N.A. 0.95 objective

preparation was transferred to 1 per cent sodium chloride at 60° C. for 90 min., as suggested by Robinow (personal communication) following Ganesan and Swaminathan⁶, to remove the cytoplasmic ribonucleic acid. After hydrolysis for 10 min. in *N* hydrochloric acid at 60°, the material was thoroughly rinsed in Sørensen phosphate buffer at pH 6.5. The preparations were stained in Gurr's R66 improved giemsa stain at one drop per ml. dilution in the same buffer. No differentiation was necessary and the material was examined as a wet mount in buffer.

The nuclei are very clearly differentiated by this method and are surprisingly large, being approximately 2 μ in diameter. The large size of nuclei, as seen by giemsa staining, may be due in part to the staining of protein precipitated around the nucleus, for giemsa contains eosin and cannot be expected to be specific for deoxyribonucleic acid (personal communication from Edward Gurr). Staining and mounting in aceto-orcein in identical material handled in the same way until after acid hydrolysis (a modification of Singleton's method⁷) shows smaller nuclei at the same loci as those seen in the giemsa method. Observation of living material with the phase-contrast microscope shows at distinct loci the nuclei and the guttule, which in this fungus are seen in lacto-phenol cotton blue preparations.

The observation reported here is contrary to Messiaen's⁸ suggestion that uni-nucleate conidia are a constant characteristic of the genera *Colletotrichum* and *Gloeosporium*. It is suggested that spore size is only rather weakly determined genetically, and may depend on the vigour of growth of the mycelium. The frequently observed production of 'mutants' with small conidia may be the result of nutritional maladjustment. Abstriction and cessation of spore growth are not necessarily fully co-ordinated in this isolate.

SOIL SCIENCE

A Warburg Vessel for Soil Samples

THE Warburg apparatus has often been used in soil research. Ellinger and Quastel¹ stated that the physical state of a moist sample permits sufficient diffusion of oxygen for aerobic biological processes. Therefore in many experiments soil samples are used in naturally moist state without making a suspension. For such experiments the conventional form of Warburg vessel is not convenient. There are difficulties in filling and washing the vessels, in removing the

samples for further analysis, etc. The side arm is useless, for it is not possible to pour off quantitatively the substrate, which must therefore be added directly to the sample at the beginning of the experiment.

Fig. 1. The Warburg vessel for soil samples.

1, Aperture for manometer; 2, aperture for glass stopper; 3, central well for alkali; 4, support for sample dish; 5, sample dish

For these reasons we use in our Laboratory a Warburg vessel modified after Johnston². The form of this vessel is shown in Fig. 1. The sample is placed on a sample-dish made from plastic or aluminium foil. All dishes have the same weight (that is, the same volume). The volumes of each pair, vessel and manometer, are adjusted to the same value (37 ml.) by means of polyethylene. 0.5 ml. of 20 per cent potassium hydroxide is put into the central well. The advantages of such a vessel are as follows:

- (1) The samples are simply weighed direct on the dishes.
- (2) The vessels need not be washed after each experiment; the washing of dishes is very simple.
- (3) Removing the sample after respiration experiment is easy.
- (4) The respiration experiment can be interrupted at any time by removing the dish with the sample which can be put into a wet-chamber in an oven for longer incubation or treated in various ways and then it can be easily returned to the vessel for further respiration measurements.
- (5) Since all vessels have the same constant, the calculation of mean values from replicate samples and of net consumption of oxygen for substrate oxidation are very easy, as well as the calculation of the respiratory quotient.

(6) Hydroxide in the central well need not be changed for five days provided no more than 25 ml. of carbon dioxide has been produced. During this time the vessels can be continuously connected with manometers and the exchange of samples can be made only by opening the front glass-stopper.

Effect of Water-stress on the Absorption of Soil Phosphorus by Wheat Plants

THERE is a limited amount of information on the soil-plant-root interaction with regard to the absorption and accumulation of phosphorus and other ions by plants.

One approach to this problem is to investigate the effect of soil water-stress on the uptake of a particular nutrient ion. From *a priori* reasoning it might be suggested that as the soil water-stress increases the coarse soil pores drain and, therefore, the cross-sectional area for diffusion of ions in the liquid phase is decreased. Hence the rate of absorption per unit area of root surface would decrease. Danielson and Russell¹ present evidence supporting this suggestion. It was found that the uptake of rubidium-86 by maize seedlings from soil decreased with decreasing soil water content. Alternatively, since most nutrient ions are intimately associated with the surface of soil colloids, it is possible that the transfer of ions in the fine pores may be the dominant path for nutrient transfer from soil surfaces to the plant root.

To test the relevance of these ideas, the effect of soil water-stress on the uptake of phosphorus by wheat plants three-weeks old has been studied using phosphorus-32 as a tracer.

Wheat plants (*Triticum aestivum* L. var. Warigo 1957) were grown on a lateritic podzolic soil from Parndarna, South Australia, in a controlled environment room. The interpretation of results was facilitated since this soil was known to be very low in total phosphorus (0.002 per cent) and to have a high capacity for phosphate fixation. Relative humidity and air temperature over the experimental period were as follows: night, 64–65 per cent and 60–62° F.; day, 48–52 per cent and 66–68° F. Day-length was 12 hr. and the light intensity at the top of the pots was approximately 2,000 ft.-candles.

Three levels of phosphorus were used: inadequate (50 p.p.m. phosphorus), adequate (150 p.p.m. phosphorus), abundant (600 p.p.m. phosphorus); 60 μ c. phosphorus-32 per gm. phosphorus-31 was used as a tracer. Other nutrients including two micro-nutrients were supplied at levels for normal plant growth. The phosphate and other nutrients were mixed throughout the soil before potting the soil in 'Pyrex' beakers (400-ml.).

Four levels of water stress were imposed as follows: soil maintained at approximately 18 per cent water content (pF 2.3) by frequent watering; soil dried to 12 per cent water content (pF 3.0) then watered to 18 per cent; soil dried to 8 per cent water content (pF 3.7), plants then harvested; or soil dried to 8 per cent water content, then after approximately 12 hr. watered to 18 per cent, dried to 8 per cent water content and the plants then harvested. The water treatments are represented by 18, 12, 8 (1), and 8 (2) per cent respectively. The water-stress treatment during the period from the harvest of the 8 (1) per cent treatment to that of the 8 (2) per cent is represented in Fig. 1 as 8 (2)* per cent. The plants began to wilt at the 8 per cent water content.

All treatments were replicated four times. Nine plants were grown in each pot and all plants were harvested within four days of beginning the water-stress treatments. Additional pots were included to determine the effect of phosphorus-32 on the growth of plants and the uptake of phosphorus. At the beginning of the water-stress treatments, the rate of evapo-transpiration at the adequate and abundant

Phosphorus-level: 50 p.p.m., +; 150 p.p.m., O; 600 p.p.m., ●
Fig. 1. Effect of soil water-stress (see text) on the uptake by wheat plants of soil phosphorus. Vertical lines indicate differences for significance at $P < 0.01$ and $P < 0.05$.

phosphorus-levels was 45 gm. per pot per day and 25 gm. per pot per day at the inadequate phosphorus-level.

Earlier workers have reported that phosphorus-32 may stimulate or retard both the growth of wheat and barley plants and the accumulation of fertilizer phosphorus²⁻⁴. It is concluded from the present experiment that any effect of phosphorus-32, at the level used, would have been to increase slightly and not decrease phosphorus accumulation by wheat plants. Phosphorus-32 had no effect on the growth of tops and roots at all phosphorus-levels.

The effect of phosphorus-level and water-stress on the rate of phosphorus accumulation is shown in Fig. 1. A statistical analysis was carried out on the results using a log ($x + 10$) transformation. The analysis showed that the rates of phosphorus uptake for the 18, 12 and 8 (1) per cent water treatments were not significantly different at any one level of phosphorus. However, the reduction in rate of uptake of phosphorus for the 8 (2)* per cent water treatment proved to be significant ($P < 0.05$ to $P < 0.01$) at the adequate and abundant phosphorus-levels. It is to be noted that during the 8 (2)* water treatment, the plants were allowed to wilt for 12 hr. The rate of evapo-transpiration following this period of wilting was significantly less than that prior to wilting. This fact, together with the evidence that the rate of uptake of phosphorus was reduced during the 8 (2)* per cent water treatment, indicates that the mechanism by which phosphorus and water are absorbed by the wheat plants had been damaged by the period of wilting. It is considered that this damage was associated mainly with the roots.

The results, therefore, demonstrate that increasing water-stress did not affect the rate of uptake of phosphorus by young wheat plants provided that the plants were not damaged by wilting.

It is concluded that the available soil phosphorus was mainly held in fine pores that remained full of water even when the plants were wilting. Since these

fine pores would not be so readily drained as coarser pores containing less phosphorus, it is suggested that the concentration of available phosphorus in the fine pores may be considerably higher than has been indicated earlier by workers using displacement techniques.

A more detailed report of this work is being prepared for publication elsewhere.

VIROLOGY

Potato Virus M and Paracrinkle

IN a recent communication under this title, Howard and Wainwright¹ confirmed earlier reports²⁻⁴ that potato plants of the variety King Edward contain potato virus S plus paracrinkle virus. The communication calls for comment and elaboration because it suggests a uniformity of infection in King Edward plants that conflicts with my experience. During the past two years I have tested many plants from seven different commercial stocks of King Edward, and most contained both viruses; but about 90 per cent of the plants in two of the stocks contained only paracrinkle virus, and one plant contained only virus S. This plant is the only one of the many hundreds tested by different workers since Salaman and Le Pelley's⁵ original work which did not contain paracrinkle virus.

The origin and behaviour of paracrinkle virus have long continued to stimulate speculation and experiment. To account for the variation in symptoms when Arran Victory was grafted with scions from King Edward, Salaman suggested that King Edward contained two viruses of which occasionally only one was transmitted⁶. However, after it became clear that his suggestion was unacceptable, it became generally accepted that only one virus was involved. For long, too, this virus was thought to be unique to King Edward potatoes and to be transmissible only by grafting. All this is now known to be untrue. Paracrinkle virus was some years ago transmitted by mechanical inoculation of sap⁷, and was found to be remotely related serologically to other viruses such as carnation latent virus, which has been transmitted by aphids, and potato virus S, which has not^{4,8}. Potato virus S occurs in many potato varieties, including Arran Victory, so there was the obvious possibility that the severe disease caused in this variety by grafts from King Edward resulted from joint infection with viruses S and paracrinkle. My primary purpose in freeing a clone of Arran Victory from potato virus S (ref. 9) was to see what symptoms paracrinkle virus alone would cause. To ensure cultures of paracrinkle virus free from virus S, I inoculated tomato plants, which are hosts for paracrinkle virus but not for virus S, with sap from King Edward leaves and later grafted scions from the

tomato plants to virus-free Arran Victory potato plants. Individual Arran Victory plants varied greatly in their reaction; some showed the typical severe paracrinkle, others showed symptoms more resembling those called leaf-rolling mosaic, and still others developed only a chlorotic blotching with little leaf deformity. The range was much the same as when Arran Victory containing virus S are infected. Hence, there is no doubt that paracrinkle virus alone can cause a severe crinkling disease in Arran Victory. Virus S seems to contribute little to the effects, and the variation in symptoms shown by Arran Victory plants infected with only paracrinkle virus probably means that this, like most other viruses, occurs in strains that differ in virulence.

Plants of several potato varieties suffering from leaf-rolling mosaic have been found to contain a virus that has been called M and shown to be closely related serologically to paracrinkle virus⁴. After Wetter and Völk found that virus M could be transmitted by the aphid *Myzus persicae*¹⁰, it seemed that the transmissibility of paracrinkle virus by aphids should be re-investigated. The tests I have made show that some stocks of King Edward contain strains of the virus that are transmitted by *Myzus persicae*, whereas from others, which gave similar symptoms when grafted on to Arran Victory plants, the aphid has failed to transmit anything. I am now surveying commercial stocks of King Edward to get some idea of the frequency with which aphid-transmitted strains occur.

The present position can be summarized briefly: most King Edward plants contain paracrinkle virus and virus S, some contain only paracrinkle and a few only S. The paracrinkle virus in different plants differs in its virulence (some strains are indistinguishable from virus M) and in its transmission by *Myzus persicae*.

⁹ Kassanis, B., *Ann. App. Biol.*, **45**, 422 (1957).

¹⁰ Wetter, C., and Völk, J., *European Potato J.*, **3**, 158 (1960).

THE discovery by Dr. B. Kassanis that 90 per cent of plants in two stocks of King Edward contained only paracrinkle virus and were free from virus S suggests that virus S entered King Edward stocks later than did paracrinkle virus (virus M). The King Edward used by us¹ was possibly derived from Salaman's original material, as the plants investigated were the descendants of occasional Red King mutants found in a stock being propagated by the National Institute of Agricultural Botany and which had originally been supplied by Salaman². Similarly, the King Edward stock investigated by Bagnall, Larson and Walker³ in the United States, and which also contained both viruses S and M, was obtained indirectly from Salaman. This suggests that the

stock of King Edward used by Salaman and Le Pelley⁴ may have contained both viruses *S* and *M*, although, of course, stocks at the National Institute of Agricultural Botany and those in the United States could have picked up virus *S* at a later date.

We should also like to take this opportunity of saying that in our previous communication¹ we have misinterpreted Bagnall, Wetter and Larson⁵. Although they state that "evidence now indicates that paracrinkle is for all practical purposes a synonym of leaf-rolling mosaic, and that both of these diseases are incited by complexes of virus *S* and virus *M*", Dr. Wetter has pointed out to us that in other parts of their paper they leave it undecided as to the parts played by the two viruses in causing paracrinkle and leaf-rolling mosaic symptoms.

Influence of a Quaternary Ammonium Salt on the Infectivity of Ribonucleic Acid from Tobacco Mosaic Virus

IN a previous paper, some of us¹ have shown that the quaternary ammonium salts of deoxy- and ribonucleic acids are soluble in organic solvents, and that by the addition of a concentrated solution of sodium chloride a precipitate of the sodium salt of the nucleic acids is obtained. It seemed interesting to us to know if the preliminary treatment of a viral ribonucleic acid with a quaternary ammonium salt produces a structural modification which can be demonstrated by the disappearance of the infectivity of the ribonucleic acid.

Ribonucleic acid preparations were obtained from tobacco mosaic virus by the phenol method of Gierer and Schramm². The solutions in 0.01 *M* phosphate contain about 0.3 per cent ribonucleic acid. The infectivity of these preparations was tested by counting the number of lesions produced on *Nicotiana glutinosa*. At the same time the following controls were made on the solutions: measurement of the sedimentation constant, determination of the molecular weight by light-scattering, serological control of the absence of viral proteins.

Simultaneously, one volume of the solution of ribonucleic acid from tobacco mosaic virus was divided into two parts; an equal volume of 0.2 per cent cetyl-trimethyl-ammonium bromide was added to each part; the precipitates of the ammonium salts of ribonucleic acid were washed three times by centrifuging their suspensions in water. Then, one of the samples was dissolved in absolute ethanol and the other one in dimethylformamide. The ribonucleic acid was precipitated in both solutions by 3 *M* sodium chloride and dissolved in 0.01 *M* phosphate. The concentration of these solutions was determined by measurements of the optical density at 260 mμ with a Jobin-Yvon spectrophotometer. The infec-

Table 1

Experiment	No. of lesions per 25 leaves			Concentration of ribonucleic acid (mgm. per ml.)		
	1	2	3	1	2	3
Ribonucleic acid control	350	166	530	1.00	1.13	1.19
Ribonucleic acid from ethanol solution	369	140	350	1.04	1.03	0.58
Ribonucleic acid from dimethylformamide solution	118	118	270	1.04	0.81	0.96

tivity tested by the lesions produced on *N. glutinosa* in both cases was compared with the infectivity of the original solution. The results are given Table 1.

It was found that 1 ml. of each solution incubated at 4° C. during 10 min. with 2 μgm. ribonuclease gives no lesions on the host.

The present results show that precipitation of the tobacco mosaic virus ribonucleic acid as a quaternary ammonium salt, its solubilization in ethanol or dimethylformamide and its regeneration as a sodium salt do not destroy its infectivity. However, it can be seen that although the infectivity is not significantly altered after treatment with ethanol, it seems to be lowered after the treatment with dimethylformamide.

These results seem to be in general agreement with those obtained by Guerritore³ on the effect of cetyl-trimethyl-ammonium bromide on the infectivity of aqueous extracts of Rous sarcoma.

MISCELLANY

A New Shadowing Material for Electron Microscopy

THE high resolving power of electron microscopes at present available makes the granularity of metal-shadowing media the limiting factor in the observation of extremely fine details of surface topography in shadowed specimens.

Platinum has probably been used more widely than any other metal because its high melting point and chemical inertness result in a very stable film. It does, however, have one disadvantage in that it forms a crystalline film which tends to appear granular at high magnification. When a platinum-shadowed specimen is examined at magnifications higher than about $\times 40,000$, the image is seen to consist of many small opaque spots. While this

granularity serves as an excellent test-object for resolution, it begins to limit detail in shadowed specimens.

In our search for a finer grained material, two things led us to try osmium oxide: (i) tissue sections stained with osmic acid often show very fine-grained, extremely opaque detail; (ii) a heavy metal oxide or mixtures of oxides might provide contrast but yet crystallize less readily than pure metals.

An osmium oxide can be obtained easily by mixing dilute aqueous solutions of osmium tetroxide and ferrous sulphate. A heavy, black, easily filterable precipitate forms at once and can be washed free of iron with dilute sulphuric acid. This black precipitate, although too dense to permit electron diffraction as formed, has been shown to be amorphous by X-ray diffraction. It can be evaporated from a tungsten ribbon to form a film that is not only amorphous to electron diffraction in the same sense that carbon is amorphous, but also exhibits intense scattering in the diffuse halos, as shown in Fig. 1a. This results in extreme opacity and requires only a very thin film to provide adequate contrast in the final image. Suitable films of osmium oxide are in fact so thin that they do not change the visual appearance of the specimen.

This black osmium oxide, on heating to red-heat in a closed container, forms brown-red crystalline osmium dioxide, identified by X-ray diffraction. Even this crystalline material forms an amorphous film on evaporation.

In the specific example described here, a small portion ($\sim 10 \text{ mm.}^3$ volume) of moist osmium oxide was placed on a tungsten ribbon filament approximately $10 \text{ mm.} \times 40 \text{ mm.}$ and evaporated through a 2-mm. pin-hole placed as close as possible to the filament. The specimen was placed approximately 8 cm. from the source and shadowed at an angle of 30° . After shadowing, the shadowed carbon film was floated in the conventional way from its mica support and picked up on a standard specimen grid.

Fig. 2b shows fine crystals of sodium laurate grown from acetone on a carbon support film and shadowed with platinum. Compare this with the same material

Fig. 1. Electron diffraction pattern of (a) an evaporated film of OsO_4 showing diffuse, intense halos, and (b) an evaporated film of platinum on a carbon support showing the crystalline nature of the material

Fig. 2. Electron micrographs of sodium laurate crystals taken at $40,000\times$ using (a) osmium oxide shadowing and (b) platinum shadowing

shadowed with osmium oxide (Fig. 2a). Notice how these crystals are more clearly outlined. The granularity in the background is quite different from that of the crystals and probably reflects the granularity of the carbon film. For our work with this type of sample, osmium oxide has proved superior to platinum as a shadowing agent.

The electron-micrographs were obtained on a Siemens Elmiskop I using a beam voltage of 80 kV., and $\times 40,000$ direct magnification. Magnification of micrographs reproduced is $\times 280,000$.

BRITISH NATIONAL COMMITTEE FOR HIGH SPEED PHOTOGRAPHY (in the Lecture Theatre, Victoria and Albert Museum, South Kensington, London, S.W.7), at 10.15 a.m.—Report on "The Fifth International Congress on High Speed Photography, Washington, October 16-23".

Friday, November 25—Saturday, November 26

BRITISH SOCIETY FOR IMMUNOLOGY (at the Wellcome Building, 183 Euston Road, London, N.W.1)—Autumn Meeting.

Friday, November 25

At 9.30 a.m.—Symposium on "Stimulation of Antibody Production". Chairman: Sir John Boyd, F.R.S.

Saturday, November 26

SOCIETY FOR THE STUDY OF HUMAN BIOLOGY (in the Department of Anatomy, University College, Gower Street, London, W.C.1), at 10 a.m. and 2.15 p.m.—Symposium on "Recent Developments in the Study of Characters of Anthropological Importance".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

ASSISTANT CATALOGUER (graduate, preferably with library experience) in the SOLOMON SECTION of the University Library—The Registrar, The University, Manchester (November 28).

OFFICIAL FELLOW IN MATHEMATICS—The Principal, Hertford College, Oxford (November 28).

LECTURERS (2) (with good academic qualifications and industrial or other experience in one of the following fields: electric power engineering, electrical machines, electrical measurements, control engineering, or microwave engineering) in the DEPARTMENT OF ELECTRICAL ENGINEERING—The Registrar, The University, Leeds 2 (December 2).

READER (with a degree in pharmacy, and the qualifications and experience to direct research and postgraduate work in the physical aspects of pharmaceuticals) in GENERAL PHARMACEUTICS—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (December 2).

RESEARCH FELLOWS (honours graduates in chemistry with interests in physical chemistry) in POLYMER CROSS-LINKING in the Department of Textile Chemistry—The Registrar, Manchester College of Science and Technology, Manchester 1 (December 3).

ASSOCIATE PROFESSORS IN MATHEMATICS AND APPLIED MATHEMATICS at the University of Cape Town, South Africa—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (South Africa and London, December 5).

SENIOR LECTURERS AND LECTURERS IN MATHEMATICS at Monash University, Clayton, Victoria, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 5).

ASSISTANT LECTURER (preferably with experience in teaching and research, and with training in physical chemistry) in CHEMISTRY—The Secretary, The Medical College of St. Bartholomew's Hospital, West Smithfield, London, E.C.1 (December 10).

DEMONSTRATOR IN SMALL ANIMAL MEDICINE AND SURGERY—The Registrar, The University, Liverpool (December 10).

BIOPHYSICIST in the DEPARTMENT OF MEDICINE, University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 16).

LECTURER (preferably qualified in physical geography) in GEOGRAPHY at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 19).

LECTURER IN PSYCHOLOGY—The Registrar (Room 22, O.R.B.), The University, Reading (December 31).

CIBA FELLOWSHIPS to enable graduates of universities of the U.K., Northern Ireland and Eire (who may be at present either at the university or in industry) to carry out research at Continental universities in chemistry, physics or some other allied scientific subject—The Ciba Fellowship Trust, Ciba (A.B.L.), Limited, Duxford, Cambridge (January 16).

CHAIR OF PSYCHOLOGY in the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, January 31).

ASSISTANT BIOCHEMIST (with a first- or second-class honours degree in chemistry or biochemistry) in THE AREA PATHOLOGY LABORATORY—The Administrative Officer, Stoke Mandeville Hospital, Aylesbury.

ASSISTANT LIBRARIAN (Associate of the Library Association, and preferably with a knowledge of French and German) in THE DEPARTMENT OF FORESTRY—The Librarian, Department of Forestry, South Parks Road, Oxford.

ASSISTANT (preferably with a medical qualification and previous laboratory experience) in THE DEPARTMENT OF BACTERIOLOGY, for duties which will include some teaching and virus research—The Secretary, University College Hospital Medical School, University Street, London, W.C.1.

CHEMIST or PHYSICIST (with a first- or good second-class honours degree in chemistry or physics, and preferably Ph.D. or equivalent research experience in the following fields: (a) irradiation metallurgy; (b) ceramics; (c) fluid flow and diffusion through porous materials; and (d) radioactive measurements), to lead a team in experimental work concerned with aspects of radiation and thermally induced changes in structural materials, radiation dosimetry and fuel burning—The Personnel Manager (1778/34), U.K.A.E.A., A.E.R.E., Harwell, Didcot, Berks.

EXPERIMENTALIST (with G.C.E. at "A" level, H.N.C. or equivalent and appropriate experience) in THE PROTON PHYSICS GROUP of the Nuclear Physics Division, for work associated with the investigation of various methods, such as plating and vacuum evaporation, for producing thin targets for exposure in the proton linear accelerator and also to work on nuclear detectors and to participate in the experimental work of the group which is using the P.L.A. for studying nuclear structure—The Personnel Manager (1824/34), U.K.A.E.A., A.E.R.E., Harwell, Didcot, Berks.

LABORATORY STeward, Grade I (with a higher national certificate or higher national diploma in electrical engineering or physics, or equivalent qualifications), to undertake the operation and servicing of the new Philips B.M. 100 electron microscope and of X-ray diffraction equipment, and to assist in the maintenance and servicing of nucleonic counting equipment and general laboratory duties—The Clerk to the Governors, Plymouth and Devonport Technical College, Education Office, Cobourg Street, Plymouth.

LECTURER IN AERODYNAMICS; and an ASSISTANT LECTURER IN AERODYNAMICS OR AERO/SPACE PROPULSION, to engage in B.Sc., Dip. Tech. and postgraduate courses and in research—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

MYCOLOGIST (with Ph.D. or equivalent degree), to carry out diagnostic work for the hospital (including collaborative research work with the clinical departments) and research in air-borne fungi in conjunction with the Department of Allergy—The Secretary, Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, Norfolk Place, London, W.2.

READER (with high academic qualifications and research or industrial experience) in FLUID MECHANICS OR AERO/SPACE PROPULSION—The Secretary, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

RESEARCH ASSISTANT (graduate, not necessarily in a science subject) WITH THE DATA ANALYSIS GROUP, to assist with, and then take charge of, an electronic measuring machine and teleprinter recording data from interactions of high energy particles in a bubble chamber—The Administrative Assistant, Physics Department, The University, Birmingham 15.

RESEARCH ASSISTANT, for chemical and radiochemical analytical work on minerals—Dr. J. R. Butler, Geology Department, Imperial College of Science and Technology, London, S.W.7.

LIBRARIES AND LIBRARY SERVICE IN BRITAIN

ALTHOUGH the question of scientific and technical libraries was virtually ignored in the recent annual report of the Advisory Council for Scientific Policy, a full session of the Home Universities Conference in December 1959 was devoted to a discussion on university libraries. One of the participants in that discussion, Mr. B. S. Page, was this year's president of the Library Association, and in his annual address to the Association at Scarborough in September—when Dr. D. J. Urquhart outlined the ideas and motives behind the development of the National Lending Library for Science and Technology—he stressed once again the human aspect of librarianship and the demands made on the librarian for scholarship, as well as for human understanding and imaginative insight into the needs of the users of his library. That was, in fact, one of the dominant notes struck in the discussion last winter at the Home Universities Conference*, which was particularly concerned that in the planning and organization of a university library the point of view of the reader, and indeed his weaknesses, should not be ignored. Here, perhaps, as nowhere else, the value of 'browsing' is greatest and special efforts are justified to ensure the maximum access. Prof. J. M. R. Cornack quoted with approval Justin Winsor's principle that books should be used to the largest extent possible and with the least trouble, and observed that it was often the chance find on the shelves that was most useful.

It should not be supposed that either the Advisory Council for Scientific Policy or the University Grants Committee is likely to be altogether unmindful of the human aspects of an adequate library system, whether in the universities or elsewhere, or to forget that however adequate the provision made, its effective use will depend to a great extent on the men and women who operate the service. Men and women of the high calibre and enthusiasm desired will not be forthcoming unless they are given both the tools for the job and accorded the status and respect that go with the scholarship and administrative responsibility involved. These professional demands are growing, and it is important that when the physical needs of university libraries and of a national library service, of which it should be remembered university libraries form an indispensable part—they supplied 28,611 books to the National Central Library in 1959–60 as against the 12,793 they received—are steadily growing, this aspect is not overlooked. Indeed, the co-operation which is essential if an adequate national system is to be developed itself makes considerable demands on the personality and administrative ability of the

librarian. It is not simply a matter of techniques and mechanical devices.

The latter, however, is the only aspect to which the Advisory Council on Scientific Policy refers in the section on library work in its current report. Recognizing the immensity of the problem created by the enormous growth of the output of scientific literature in all countries, the Advisory Council suggests that this problem will continue increasingly to impede the utilization of scientific and technical information, and so progress, unless it is recognized as meriting research in its own right; techniques must be devised for recording and presenting scientific information in a form in which its significance can be most readily appreciated by those who have to use it. The Council considers that serious research into the whole problem of collation and dissemination of scientific information should be undertaken forthwith, possibly under the auspices of the new National Science Lending and Reference Libraries and in association with international efforts in this sphere.

The Advisory Council does not mention the Association of Special Libraries and Information Bureaux, of which the terms of current grant from the Department of Scientific and Industrial Research require it to undertake research into the field of documentation; but at least its remarks show that the Advisory Council is aware both of the magnitude of the problem and of the need for co-operation up to the international level. The enormous increase in the output of scientific literature is, however, not reflected in the returns for library expenditure given by the University Grants Committee. While annual expenditure on libraries had risen from £156,000 in 1925–26 to £255,000 in 1938–39, £988,000 in 1951–52 and £1,979,945 in 1959–60, the doubling of expenditure during the past decade has been spread fairly evenly over the different items. Expenditure on salaries and wages rose from £527,238 to £1,070,466; on books from £202,567 to £434,254; and on periodicals from £118,702 to £231,458. The percentage which library expenditure represents to the total expenditure remains at 3.8.

It is, however, the figures for the expenditure of individual libraries that are most illuminating. Apart from the University of London, with expenditure on books of £91,817 (£12,301 was for the Central Library and £13,526 for University College), the only university libraries in Britain spending more than £20,000 on books in 1959–60 are those which are entitled to receive on demand a copy of every published book in the United Kingdom, namely, Oxford (£62,088) and Cambridge (£28,734). Indeed, outside Scotland, where Edinburgh, Glasgow and St. Andrews spent more than £19,000, £18,000 and £16,000, respectively, on books, only Manchester, Leeds, Birmingham, Durham, Liverpool and Sheffield spent more than

* Association of Universities of the British Commonwealth. Conference of the Universities of the United Kingdom—Report of Proceedings. Pp. 104. (London: Association of Universities of the British Commonwealth, 1960.) 5s.

£10,000. The picture with expenditure on periodicals is similar. A quarter of London's expenditure of £63,173 was for the Central Library and that of University College. The University of Cambridge spent £17,400 on periodicals and the University of Oxford £15,461; only three other universities spent more than £10,000—Glasgow, Manchester and Birmingham—though Edinburgh spent only just short of this figure. Furthermore, the proportion which library expenditure bears to the total expenditure also varies widely, especially among the English universities—from 8.3 per cent for Oxford and 7.2 for the Durham Colleges of the University of Durham to 2.0 for King's College of the same University and 0.9 for the Manchester College of Science and Technology; and within the University of London, which averages 3.5, from 36.5 for special institutions like the Courtauld Institute of Art, 7.7 for the London School of Economics and also for the Central Library, to 0.9 for the Imperial College of Science and Technology—a figure attributed to the access enjoyed to the Science Library.

How far these figures are really comparable cannot be judged from the tables supplied by the University Grants Committee, but clearly some account must be taken both of the existing resources of a university and its size. Apart from the fact that some figures like that for the Manchester College of Science and Technology are clearly abnormal—in this instance through inclusion under miscellaneous university expenditure of a surprisingly high figure for interest on overdrafts, etc.—it is common knowledge that expenditure on books for departmental libraries is sometimes included under departmental expenditure and sometimes under library expenditure. It is noteworthy that in the new institutions such as the University College of North Staffordshire (5.7), University of Hull (5.4), University of Exeter (5.0), University of Leicester (5.3) and University of Southampton (4.8) the percentage of library expenditure to total expenditure is above the average. Mr. K. W. Humphreys, librarian of the University of Birmingham, in opening the discussion at the Home Universities Conference, pointed out that already expenditure on libraries exceeds the total Government grant to universities a generation ago. Even at the existing rate of growth, £16 million might well be required for libraries by the late 'eighties, and if any attempt is made to overtake the rapid increase in student population after the mid 'seventies, libraries should absorb an increasing proportion of the general university grant—possibly 10–15 per cent by the end of the century.

So long ago as 1921, the University Grants Committee expressed the view that the character and efficiency of a university might be gauged by its treatment of its central organ, the library. "We regard the fullest provision for library maintenance as the primary and most vital need in the equipment of a university. An adequate library is not only the basis of all teaching and study, it is the essential condition of research, without which additions cannot

be made to the sum of human knowledge." In its report on "University Development" two years ago, the Committee recognized that a large part of university expenditure for research of all kinds is expenditure on libraries, and that although between 1951–52 and 1956–57 expenditure on libraries had increased by 64 per cent, this was largely due to increased costs, and the real increase was less than 10 per cent.

Mr. Humphreys recognized that the new National Lending Library for Science and Technology should relieve some of the pressure on the universities inter-lending scheme and provide copies of out-of-the-way periodicals so that science and technology can be better served; but even this passing reference indicates that the universities cannot stand right outside the library services of Great Britain, and Dr. Urquhart, in speaking at Scarborough, reiterated his view that demands for inter-library lending are likely to grow. Mr. Humphreys believes that while the undergraduate population has increased, their book buying has declined; this has been challenged, but even if the Anderson Committee's recommendation that an allowance for books should be included in all maintenance grants and the figure made public has its full effect, the university library is unlikely to benefit substantially. As Mr. Humphreys himself pointed out, the best hope of relieving pressure lies in co-operative action, in the adoption where possible of new techniques and in skilled administration—the same factors that alone can ensure the most efficient use of whatever resources may be available.

Some of these problems were indicated in an illuminating address by Prof. J. M. R. Cormack, who, approaching the problem from the reader's point of view, displayed very clearly not merely some of the opportunities for improvement but also the pitfalls that attend the unwary adoption of new gadgets. It was left, however, for Mr. Humphreys, in replying to the discussion, to refer to some of the implications of the suggestions which had been made in regard to such matters as inter-university co-operation and longer hours of opening. Questions of staff and of finance as well as education may be involved, running well outside the university library itself.

This discussion at last year's Home Universities Conference shows clearly that the universities themselves are well aware of the importance of the university library and the vital contribution it makes to the efficiency with which a university performs its functions of teaching and research. Moreover, those in charge of the university libraries are obviously alive alike to the varied needs of the users of those libraries, whether they be undergraduates or members of the university's staff; and they are no less aware of the important place which the university library holds in the library system of Great Britain as a whole. The way in which criticism advanced in the course of the discussion was received is no less encouraging; weaknesses in the university libraries should not be charged primarily against those

responsible for their administration, but against those responsible for failure to provide the resources commensurate with the growing demands which the universities and the community make on the university libraries.

How far those weaknesses are the responsibility of the University Grants Committee itself or of individual universities can scarcely be judged from the published evidence. All that can be said is that, judged in terms of total expenditure on libraries, expenditure on books, periodicals or staff, or the proportion which library expenditure bears to university expenditure as a whole—or on the expenditure per head of staff and student as noted by Dr. W. S. Mitchell in the discussion—the expansion of expenditure on libraries falls a long way short of that required to meet the ideal formulated by the University Grants Committee more than a generation ago. What is clearly needed is much firmer support from the University Grants Committee and also a wider public understanding generally.

Mr. B. S. Page, in his presidential address to the Library Association, manifestly sought to enlist such support and understanding from the Library Association, and there should be other opportunities in the present Parliamentary session which might be used. In spite of the fact that the Roberts Committee on the structure of the public library service was singularly indifferent to the part played by the universities, that omission should be rectified whenever the Minister of Education advances his proposals for action on the report, though that is unlikely to be in the present session—a fact which itself indicates how little importance the Government attaches to the provision of an adequate library service. It is, however, on the Advisory Council for Scientific Policy and on the Minister for Science that the major responsibility rests. Dr. Urquhart's address to the Library Association shows that he is aware of the inter-relationships between the university libraries and the new National Lending Library for Science and Technology, and that he is indeed anxious to foster co-operation and on the proper basis—of ascertained fact. Dr. Urquhart, however, is only responsible for the lending side, and the National Reference Library for Science and Technology also comes into the picture.

It is only as the Minister and the Advisory Council ensure that that project is vigorously and adequately developed, and due account taken not only of the resources and functions of the university libraries and of those of the colleges of technology, but also of the technical libraries provided by at least the major public libraries, that we can hope to see, inside and outside the universities, a library service adequate to meet the needs of the whole community in this age of rapid technological change. It has to be admitted that so far the Minister and the Advisory Council have shown little sign that they are aware of the immensity of their responsibility in this field, or of its far-reaching implications. One remark at least in a discussion at the Library Association's

Conference at Scarborough should bring that responsibility home. Commenting on Mr. M. C. Pottinger's address on "Libraries in the Soviet Union", Mr. L. L. Ardern, of the Manchester College of Science and Technology, remarked that the need for a British Scientific Information Centre had been very fairly illustrated, and Mr. Pottinger fully concurred. When all recognition has been made of Dr. Urquhart's readiness to see the new National Lending Library for Science and Technology functioning as part of a truly national system, it is difficult to reconcile its location in Lincolnshire, or the tardiness with which the corresponding reference library project is developing, with any sense at the centre of the inter-relationships inherent in a national system, or of the savings which could have been achieved by real planning in relation to the resources of the whole country. Little account seems to be taken of the contributions which the university libraries and those of the learned societies and professional institutions, as well as the National Central Library and the public libraries themselves, could make. In few other fields is piecemeal development more costly in terms of finance and of goodwill.

DARWIN PARTIALLY APPRAISED

Darwin's Place in History

By Prof. C. D. Darlington. Pp. ix+101. (Oxford: Basil Blackwell, 1959.) 9s. 6d.

PROF. DARLINGTON is perhaps unfortunate in the fact that his essay, dated February, was not published until the late December of 1959, the year when a spate of publications celebrating the centenary of the "Origin" almost overwhelmed the reader. His thesis does not therefore strike home with the originality which its initial composition presumably required. Charles Darwin is shown in this publication to have used the work of precursors in the field of transmutation without sufficient acknowledgment; to have equivocated over the problem of the origin and transmission of variation in Nature; to have "failed to recognize or to relate his own ideas . . . with those of others working in the same field"; and to have used to help achieve his admitted "success in mass conversion" to the evolutionary hypothesis "a flexible strategy which is not to be reconciled with even average intellectual integrity". Darwin is given credit for independence of thought, but this he owed not to any personal quality but to the fact that "by independence of economic position, he had a unique advantage over all his contemporaries".

This remarkable and original view is presented with a pretty wit and a challenging directness. Nobody reading this pamphlet could fail to be stimulated by it. The author is master of the telling phrase, for example, when he refers to Darwin "assembling his forces with a prudent strategy without which he would never have won his battle"; his remark that historians of science "often believe what the discoverer writes about his own discoveries, which, as we see, is not a wise thing to do"; and his comment on Samuel Butler's last anti-Darwin

book "its title *Luck or Cunning* referred not to the causes of Darwin's success but to Butler's views on evolution".

Darlington makes a clear distinction between 'hard' and 'soft' heredity. Hard heredity implies selection after variation and soft heredity direction before variation. In an appendix he supplies an anthology of great value for the student from the writings of protagonists of both views. It is fortunate that the original language is sometimes given so the reader may reach his own conclusion concerning the propriety of translating "genitalia corpora" in Lucretius as "genetic bodies".

Authors are frequently presented in language, admittedly colourful, which carries undesirable overtones of sense acquired in more recent usage. Lawrence, for example, is credited with the use of 'mutation' though he actually wrote "native or congenital varieties". It is somewhat disconcerting to find that Prof. Darlington seems unaware that until the 1850's the word evolution was used in an embryological as well as in its later (post-Darwin) transmutation sense, for he comments (p. 35) that T. H. Huxley's (1878) essay on the history of evolutionary theory was "curiously combined with a history of embryology" although one of his own quotations from Spencer (p. 83) speaks of the physiologist "who knows that every individual being is so evolved" from "their earliest condition" when "the germs of all plants and animals whatever are so similar". Nor is it correct to imply that Darwin did not begin to write the "Origin" until he received Wallace's essay for publication, or that Darwin considered all differences between parents blended in their offspring. On this latter point, Darwin in 1837 wrote opposite Lyell's phrase, "Some acquired peculiarities of form, structure, and instinct are transmissible", the comment "with no tendency to go back" and "the very character of species is character being heredity", an unexceptionable statement of 'hard' heredity¹.

Erasmus Darwin as "the great precursor" is well presented in this pamphlet, though it might be made clear to the reader, since Prof. Darlington places so much weight on Charles's reading of his grandfather's works while at Edinburgh, that he arrived there a boy of sixteen and stayed for less than two years.

The claims of Lawrence as a precursor and advocate of 'hard' heredity are seriously advanced by Darlington. Lawrence's lectures, published in 1819, argue at length, and somewhat repetitiously, to demonstrate "that the human species, therefore, like that of the cow, sheep, horse, and pig, and others, is single, and that all the differences, which it exhibits, are to be regarded merely as varieties". There is no evidence that Darwin read this work before 1847, when his ideas were already fully developed. His copy, at Down House, of these lectures is the 1822 Benbow edition. The notes on the back flyleaf include "Zool. acceptance of Species etc. 225-232", but no comment in written on these text pages. What is useful in Lawrence and Prichard was most likely transmitted to Darwin through Lyell's works, of which Darwin wrote to Horner (August 29, 1844): "I always feel as if my books come half out of Lyell's brains & think I never acknowledge this sufficiently . . .". It seems Darwin did not follow up all Lyell's references until a comparatively late date. He, perhaps justifiably, felt he could trust Lyell.

I have said enough about Prof. Darlington's approach to the writing of history for the reader to realize the need for caution in accepting such state-

ments (p. 52) as: "The cellular basis of reproduction and heredity . . . had been revealed in the previous (to 1864) thirty years". The first published description of the fusion of the fertilizing sperm with the egg and the subsequent behaviour of the male and female pronuclei was given in 1874 by Auerbach from his study of nematode worms. Weismann first published on heredity in 1883, one year after Darwin's death.

This sketch of Darwin's place in history seems to have begun as a brilliant impression; unfortunately, the selective heightening of some strokes by the author has caused the sketch at times to become a caricature. It seems as if the author was using opera glasses the wrong way round, so shrunken and inconspicuous is Darwin's image. The reader often has cause to wonder why so much trouble should be taken to demolish such a minor figure. If, in the pursuit of an answer, he turns yet again to Darwin's writings, good will result from this publication.

MEASURING MOLECULES

Molecular Structure

The Physical Approach. By J. C. D. Brand and J. C. Speakman. Pp. viii+300. (London: Edward Arnold (Publishers), Ltd., 1960.) 30s. net.

BRAND and Speakman have set out to give an account of the physical methods of elucidating molecule structure "written at a level suited to the honours student, or to the research worker in some other branch of Chemistry". Students in Glasgow must be strong men, however, if the mathematical level of this volume causes them no trouble. To meet the irreducible representations of a group by p. 26 seems over-demanding for a chemistry student. Like the authors, I certainly wish that all chemistry students had this sort of understanding of the methods of studying molecular structure; but to start with "Brand and Speakman" would be to push most of them in at the deep end. It is difficult to avoid a comparison with P. J. Wheatley's recent book, "The Determination of Molecular Structure", which covers similar ground. Wheatley kept the mathematics to a much simpler level and provided rather more examples of chemical interest, with numerous illustrations of the shapes of molecules. For an introduction to the subject, students would therefore be well advised to start with Wheatley. The abler ones could then pass to Brand and Speakman, who will take them much closer to the mathematical techniques which are the necessary stock-in-trade of the research investigator. By comparing and contrasting the two books, which often complement each other, good students could reach an excellent appreciation of the subject.

The reader who is not troubled by the mathematics will find Brand and Speakman's account in general admirable. The headings of the various chapters on physical methods will serve to show the range they cover: "The Rotation of Molecules", "Nuclear Resonance Spectra", "The Vibration of Molecules", "Anisotropic Polarizability and the Raman Effect", "Crystal Structure Analysis", and "Electron Diffraction". The stage for these is set by two chapters on symmetry and elementary wave mechanics. The latter, which,

incidentally, has a clear and sound postulatory approach to the subject, provides the quantum mechanical results needed for the spectroscopic chapters. Almost always the book is thorough and clear. The chapter on nuclear resonance spectra, for example, covers nuclear magnetic resonance in solids and liquids, pure nuclear quadrupole resonance and nuclear quadrupole coupling in pure rotation spectra. A separate chapter on the electron diffraction of gases is especially welcome, as the capabilities of this powerful method of structure investigation have been far too little appreciated in Britain. On the other hand, the discussion of electron and neutron diffraction by crystals, which is part of the chapter on crystal structure analysis, is perhaps too brief. Otherwise this chapter gives a very readable account of the methods and of the range of the results of modern X-ray crystallography.

The final chapter of appraisal and conclusions draws the various threads together and makes useful comparisons of the results of the different methods. The last sentence, however, is very curious. As the conclusion of a contrast of diffraction and spectroscopic techniques, it reads: "Because the spectroscopic methods look towards the wave function, they constitute the most fundamental approach to molecular structure". The implication that diffraction techniques are unrelated to the wave functions is, of course, quite false: a glance at James's standard treatise "The Optical Principles of the Diffraction of X-rays" will show the closeness of their connexion. This extraordinary remark is perhaps the result of a certain unbalance in the authors' treatments of spectroscopic and diffraction methods. They give the wave mechanical fundamentals of spectroscopic theory in some detail, but do not even sketch the corresponding parts of diffraction theory: the key relation $\rho = \psi^* \psi$ is unmentioned.

Nevertheless, "Brand and Speakman" is excellent value. Its price should induce many students to make the mathematical efforts necessary to achieve a deep understanding of the subject.

Minor flaws noted include misprints in the character table for the point group T_d , where the translations and rotations are assigned to the wrong representations. Fig. 3.5.1 omits any scale for z .

D. W. J. CRUICKSHANK

PROGRESS IN NUCLEAR PHYSICS

Progress in Nuclear Physics

Vol. 7. Edited by Prof. O. R. Frisch. (Progress Series.) Pp. vii+326. (London and New York: Pergamon Press, 1959.) 84s. net.

THE volume under review covers the following topics: "The Bubble Chamber" (D. V. Bugg), "Resonance Fluorescence in Nuclei" (F. R. Metzger), "Spallation" (B. G. Harvey), "Optical Model for Nuclear Scattering" (A. E. Glassgold), "Measurement of Helicity" (L. Grodzins), and "Weak Interactions" (J. J. Sakurai).

Though an article on the bubble chamber was published in the same series two years ago, a progress report seems indicated in view of the technical advances made and the realization that here we have indeed one of the key instruments for future high-energy research. The theory of chamber operation, the practical considerations associated with various

liquids, some design features of operating chambers and much of the auxiliary equipment such as magnet characteristics, illumination, photographs and track-measuring devices are included in the account. Since the bubble chamber produces prolific amounts of detailed information, great efforts will be required to develop methods to extract the information contained in the photographs at the same rate as the chamber records events; here the author might have been more generous in attacking such a formidable task, particularly in so far as the general principles are concerned. It would have been useful to provide more information of the financial side of a bubble chamber project.

Dr. Glassgold's review is most ably done; unfortunately it does not include in the analysis the very important results of polarization effects obtained by Dr. L. Rosen at Los Alamos. This and some other aspects might well be a good topic for a future contribution to this series. Again, the article on resonance radiation, though very well done, is just a trifle stale as it misses the impact of the Mössbauer method in the field. The well-written but extensive review on spallation convinces the reader that this field seems a bit dull and is by now probably exhausted. Choice of the highlights of the volume may be a matter of taste, but I feel few will dissent if this distinction is confined to the two articles, "Measurement of Helicity" (75 pages) and "Weak Interactions" (71 pages). Clarity, completeness (including a discussion on unsolved problems in Dr. Sakurai's article) and lively language all contribute to the joy of reading these surveys.

The literature references seem to include the papers up to 1958, but not 1959; the volume is therefore slightly out of date.

E. BRETSCHER

GAS CHROMATOGRAPHY

Gas Chromatography

By A. I. M. Keulemans. Second edition. Edited by C. G. Verver. Pp. xxi+234. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1959.) 60s. net.

THE first edition of Keulemans's "Gas Chromatography", published in 1957, was a landmark in the subject. Prof. Keulemans had played a leading part in the development of both the experimental and theoretical parts of the technique, and was one of the first to direct attention to the importance of operating columns under optimum conditions. The theoretical sections were therefore particularly good and the practical sections gained from a wide practical experience. Since 1957, gas chromatography has developed tremendously, the number of papers having risen from a few hundred to more than three thousand, and in 1958, when the revision of the first edition was presumably being carried out, two highly significant advances occurred. These were the invention of several highly sensitive detectors based on the ionization of the eluted vapours, and of capillary columns. It is now clear that these advances have so altered our outlook on gas chromatography, its aims and potentialities, that any text written before 1958 would require extensive revision to bring it up to date. The revision which has taken place between the first and second editions of "Gas Chromatography" now appears inadequate, although, to be fair, this

was probably not obvious at the time. Only four pages are devoted to the ionization detectors and only four to capillary columns. The Golay equation is not mentioned and there is little in the way of practical information on the operation of capillary columns. There is only the briefest of sections on temperature-programmed gas chromatography and nothing on preparative gas chromatography. Recent work on the improvements in efficiency of packed columns is treated rather sketchily and the katharometer theory remains unaltered in spite of the realization that forced convection is important in determining both the sensitivity and the stability of katharometers. Most of the theoretical sections are still first class, but even here one feels that an improvement could have been effected by more concise presentation now that the initial barriers to the mathematics have been broken down.

My chief impression of the second edition is therefore that modern developments, major and minor, have been given too little space. I am disappointed that so eminent an authority should have failed to make the same mark with his second edition as with his first.

Nevertheless, Keulemans' book is still the best on the subject and can be warmly recommended to those who do not possess the first edition. Those who do must still await an up-to-date account of recent work.

JOHN H. KNOX

LIPIDS AND LIPOPROTEINS

Lipide Chemistry

By Dr. Donald J. Hanahan, Dr. Frank R. N. Gurd and Prof. Irving Zabin. Pp. ix+330. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1960.) 80s. net.

AFTER a short introduction, the main chapters have the following sequence: isolation and purification, phosphoglycerides, phosphoinositides, sphingolipids, minor phospholipids, simple lipids, association of lipids with proteins, some naturally occurring lipoproteins. The chapter on sphingolipids is by Prof. Zabin, the last two chapters by Dr. Gurd, and the rest of the book by Dr. Hanahan. Each is an acknowledged authority in his field. Discussion is limited essentially to the chemistry of the lipids present in mammals, while lipid metabolism is the subject of a companion volume.

The three authors differ greatly in style and in approach to their topics. Dr. Hanahan mentions that much of his material has been used for graduate lecture courses, and his chapters gave the reviewer an impression of expanded lecture notes with rather slipshod continuity. On the general level, it is curious to find simple glycerides discussed after the more complex phosphoglycerides, while the minor phospholipids described are all phosphoglycerides and their inclusion with these would have facilitated orderly development. On a more detailed level, there are many points at which the reader is halted by an apparently unjustified conclusion from the preceding argument, later to find the missing material. Two examples must suffice. Near the top of p. 51 "convincing evidence" of optical activity is mentioned, but the relevant data are given near the bottom of the page. About the middle of p. 188 reference is made to "the above chromatotropic acid method", which leaves the reader guessing until the top of p. 189. Sometimes

there is discrepancy with what has been said earlier; for example, on p. 44 it is reported that β -glycerophosphoric acid is converted quantitatively into the α -form by boiling acid, but on p. 45 we learn that an equilibrium mixture results. A section on p. 73 opens with the words "When confronted with the information cited in Chapter 1". This so-called information is simply a generalized statement repeated almost word for word on p. 73. The whole of Dr. Hanahan's material would benefit from careful editing, even to the reference points in the text for the footnotes on pp. 78, 88 and 91. It is, nevertheless, a valuable source of up-to-date information in a rapidly developing field.

The other contributions are superior in orderly approach and clarity of expression. Presumably they were specially written and not adapted from lecture material. The chapter on sphingolipids is agreeably concise. The two chapters on lipoproteins make up more than one-third of the book and are wholly admirable. Indeed, they redeem this beautifully produced book from the level of the adequate but uninspiring.

J. A. LOVERN

SCIENCE IN THE PRIMARY SCHOOL

Approaches to Science In the Primary School

Edited for the New Education Fellowship by Evelyn Lawrence, Nathan Isaacs and Wyatt Rawson. Pp. xiii+143. (London: Educational Supply Association, Ltd., 1960.) 10s. 6d. net.

WITH the recent increasing development of science in the secondary school, a growing need has been felt to prepare the way in the primary school. A committee was appointed by the New Education Fellowship to "consider the place of direct observation and experiment in the primary school".

This committee felt that the introduction of science to the curriculum could cause difficulties for the teachers, either through a feeling of inadequacy in themselves or through lack of ideas of approach, so this book was compiled for the teacher. It is not a suggested syllabus, nor is it merely a collection of articles, even though each chapter is written by a different author, including practising teachers who have contributed articles on their own approaches and experiences with different age-groups.

The book deals with the aims and the objects of starting science in the primary school. It explains that such teaching is a necessity not only for the scientifically minded but also for any child who is to grow up in this day and age.

Two chapters are entitled "Diverse Roads to Diverse Sciences": these titles speak for themselves. A further chapter deals with making the most of what one has, whether in the town or the country. Another deals entirely with teachers' needs and difficulties, and suggestions on how to overcome them. One section of a chapter offers leads for science lessons from the children's own, very commonplace, questions. There is a bibliography both for the teacher and the pupil.

The book makes interesting reading, and should act as a helpful guide to the teacher with any doubts.

B. J. G. MAITLAND

Chromatographic Reviews

Progress in Chromatography, Electrophoresis and Related Methods, Vol. 2. Edited by Michael Lederer. Pp. viii + 195. (Amsterdam: Elsevier Publishing Company; London: D. Van Nostrand Company, Ltd., 1960.) 46s.

APPEARING about a year after the first, this second volume contains six articles. In a preview of gas-liquid chromatography (C. J. Hardy and F. H. Pollard), principles and techniques are dealt with and there are 600 references. Despite the vast literature on the subject, the authors have succeeded remarkably well in covering the essentials so adequately. Starch-block electrophoresis (H. Bloemendahl) is a comparatively short article which provides clear practical details and reviews applications of this important method. G. Biserte and associates write about the paper chromatography of dinitrophenyl amino-acids. This is a most satisfying article, for not only does it supply full data about solvent systems and R_F values but it also includes details of the preparation and properties of dinitrophenyl amino-acids and describes the dinitrophenylation of proteins and peptides with subsequent treatments for liberating and examining the labelled terminal amino-acids.

Flavonoid pigments are covered by J. H. Harborne, who deals clearly with the paper chromatography of the many substances belonging to this class. The article on human haemoglobin (H. K. Prins) is a most interesting survey of electrophoretic and chromatographic techniques which have been used with such striking success in the past ten years for demonstrating and isolating a large number of hitherto unknown haemoglobins. Finally, E. Hayek reviews a special kind of chromatography of inorganic substances based on adsorption and precipitation mechanisms. Like the first volume, all the articles are in English, and were originally published in the *Journal of Chromatography*. This second volume is full of interest, is up to date and maintains the high standards of its predecessor.

R. CONSDEN

Review of Studies in the Flow of Information among Scientists

Vol. 1: Text. Pp. v + 62. Vol. 2: Tables. Pp. ii + 48. (Washington, D.C.: Bureau of Applied Social Research, Columbia University, 1960.) Available from the National Science Foundation, Office of Science Information Service, Washington, 25, D.C.

THIS review, which was commissioned by the National Science Foundation, is not a review in the ordinary sense. It is rather part of the raw material for such a review. The authors have assembled the statistical material of a number of reports on the flow of information to scientists under the different questions considered. They come to no conclusions. Their purpose seems to have been to leave to others the formulating of conclusions, and only to suggest where further work might be done. The documents will be of value only as an *aide memoir* to those who are planning further surveys.

The subject of the flow of information to scientists is undoubtedly important. So far, however, the efforts to understand this process have led mainly to the collection of curious information. This has resulted in very few measures for improving the situation. The report makes no serious effort to direct attention to what might be useful and what is

not. My own paper of 1948 (which is the earliest covered by the survey) is extensively quoted in the tables, although, so far as I know, it never led to any positive action except more surveys. My paper of 1958, which was a detailed survey of the use of serial literature in the Science Museum Library in 1956, is only referred to in one table. But this later paper was used to decide what literature in the Science Museum Library should be duplicated in the National Lending Library for Science and Technology.

Two important results on the flow of information to scientists which we in the Department of Scientific and Industrial Research Headquarters obtained are not mentioned at all. The first was the availability of Russian scientific literature in the United Kingdom in 1956; the second was the extent to which working scientists said they could read French, German and Russian. It matters not. The first result was mainly instrumental in starting the National Lending Library. The second assisted materially in the discussions which led to the starting of the Department of Scientific and Industrial Research's Russian translating programme. Let not the cynic say from this example that in this field "Useful results lead to action. Useless results lead to learned papers". The fundamental problem is going to become more serious as the scientific effort of the world increases.

D. J. URQUHART

Some Problems of Chemical Kinetics and Reactivity

Vol. 1. By Academician N. N. Semenov. Revised and expanded by the author. Translated by Dr. J. E. S. Bradley. Pp. x + 305. (London and New York: Pergamon Press, 1958.) 50s. net.

PROF. SEMENOV'S pioneering book on chain reactions was published more than twenty years ago, and since then there has been intense activity in the study of chemical kinetics, of which there is now extensive literature. In the preface the author states that he does not think the main problems are completely solved. The number of papers published since 1950, quoted in the references, is very large, and the subject has been brought up to modern publications so far as possible. The Russian work is fully covered, but the literature of all countries has been included and older work of importance finds its place. The treatment is critical, and when complete evidence is lacking or findings are contradictory this is pointed out.

The first part of the book deals with radical reactions in three main branches: unimolecular reaction, alternative univalent free radical reactions, and reactions of biradicals. The section on hydrocarbon oxidation reports recent work, including that of Shtern, which suggests that aldehyde formation is more important than peroxide intermediates, but it cannot be said that finality has been reached in this field.

The second and third parts deal with chain reactions. There is a critical discussion of the inhibiting effect of nitric oxide. The initiation and termination of chains on walls are considered from a new point of view, which is also involved in the discussion of heterogeneous catalysis. The appendixes deal with activation energies calculated by the London method.

The translation is very good, and the book reads as if it had been written in English originally. With the later volumes, the work is one which should be carefully studied by all physical chemists.

J. R. PARTINGTON

PORPOISES AND THE BOW-RIDING OF SHIPS UNDER WAY

By ANDREW A. FEJER

Woods Hole Oceanographic Institution and Illinois Institute of Technology, Chicago

AND

RICHARD H. BACKUS

Woods Hole Oceanographic Institution, Mass.

IN recent years there has been a controversy concerning the phenomenon of porpoises dwelling almost motionless near the bows of ships under way while obtaining propulsive power from the moving vessel. In reading the papers¹⁻⁵ that have been published relative to this matter it is evident that certain observational facts have been overlooked by earlier investigators. In view of this, and on the basis of some new observations made by one of us, we would like to offer an explanation of the phenomenon of bow-riding based on a model which differs from those proposed earlier.

Since Woodcock reported his observations on 'wave-riding' porpoises in *Nature* twelve years ago¹ the several papers published concerning this subject have offered explanations given in terms of the forward-sloping surface of the bow wave—hence the term 'wave-riding'. Woodcock¹ and Woodcock and McBride² showed that the component of the submerged weight taken along the wave slope was scarcely sufficient to balance the resistance that the animal experiences as it is moved through the water. Hayes³ pointed out that near the wave surface the isobars are not horizontal and that the force due to the buoyancy (B) must therefore be normal to the slope of the wave (Fig. 1); consequently the hydrodynamic resistance (D) of the porpoise can be balanced by the component of the body-weight parallel to the wave surface ($W \sin \theta$). Scholander⁴, on the other hand, refutes this argument on the basis of drag measurements made on small, streamlined, neutrally buoyant models that were towed in the waves of a vessel. He believes⁵ that the porpoise places itself ahead of the bow wave with the tail flukes buried in the forward-facing portion of the wave (Fig. 2) in order to provide the thrust ($L_f \sin \theta$).

Observations by one of us (R.H.B.) of porpoises and their swimming and bow-riding have been distributed over the period of the past ten years, although it is only during about the last two that we have watched these charming animals with the present problem particularly in mind. These observations have been made from vessels having lengths of 100–214 ft. and speeds of 7–14 knots. None of these relatively small vessels generates conspicuous bow waves.

The animals concerned in these observations are the bottlenose porpoise, *Tursiops truncatus*; the saddleback porpoise, *Delphinus delphis*; the white-sided porpoise, *Lagenorhynchus acutus*; *Stenella styx*; and other unsuccessfully identified porpoises including several of the poorly known genus *Stenella*. The largest of these animals is *Tursiops*, which may attain a length of about 11 ft. The others are smaller, generally being, in adulthood, from six to eight feet long. These small cetaceans all belong to the sub-family Delphi-

ninae of the family Delphinidae (the 'duodecimo' whales of Herman Melville's classification). It is interesting to note that the next sort of cetacean in point of size (Melville's 'octavo' whales), the Orcinae of the family Delphinidae, most of which reach lengths of 15–20 ft. at maturity—the potheads or pilot whales, *Globicephala* spp.; the killer whale, *Orcinus*; the false killer, *Pseudorca*; *Grampus*; and the like—are not known to be bow-riders nor are cetaceans of still larger size. (The most famous of all individual bow-riders is the porpoise 'Pelorus Jack', which escorted vessels in and out of Pelorus Sound, New Zealand, during the years 1880–1912 and was granted special protection by the New Zealand Government. This animal is supposed to have been a grampus (*G. griseus*), but this is not certain. In our experience grampuses avoid close approaches to a vessel, generally not coming nearer than about 50 or 75 ft.)

Would-be bow-riders, when first observed at a distance of several hundred yards, seem to swim purposefully towards the ship for taking their stations. Sometimes porpoises thus approaching come to within 30 or 40 ft. of the ship but no nearer. On a number of occasions we have watched porpoises

Fig. 1. Model of bow-riding porpoise according to Hayes (ref. 3). B , buoyant force; D , hydrodynamic drag force; W , weight of porpoise; θ , slope of wave

Fig. 2. Model of bow-riding porpoise according to Scholander (ref. 5). L_f , hydrodynamic lift force on flukes; D , hydrodynamic drag force

approach on a nearly reciprocal heading from that of the ship, then turn sharply on to the ship's heading when the range between ship and animal was 20 or 30 ft., and be gently overtaken by the ship as they assume a bow-riding station 1-5 ft. ahead of the ship's stem.

Once at a position at the bow the animals may remain only for seconds or for as long as an hour or more. Often a group of eight or ten porpoises may join the ship together and spend 10-15 min. riding at the bow. Then the group may diminish slowly over the period of 5 min. or so as the animals drop away by ones and twos.

The distance between the ship's stem and the porpoise's flukes is usually between less than a foot to five feet. The lateral spread of bow-riders is generally about 3 ft. to either side of the stem. Sometimes when the porpoise is riding very close to the ship and is to the side of the ship's midline the flukes may be up to a foot or 18 in. behind the ship's stem. The animals are between one or two and five or six feet below the surface and may be arranged in two or even three layers. The animals rise to the surface, of course, as it becomes necessary to breathe and often leap clear, or partly clear, of the water at these times.

While one may detect the swimming motions of porpoises at close range from the ship's side, it is often very difficult to see these motions in bow-riding animals. A novice observer often suggests that this is because of the high frequency and low amplitude of the tail beats; but it appears that it is really due to the facts that: (1) at times the porpoise is not swimming at all; (2) at times the animal is swimming easily with low-frequency and low-amplitude strokes; (3) that the common vantage point of the observer at the top of the ship's stem is a poor one for detecting the vertical swimming motions of an upright porpoise.

Often one sees individuals proceeding on a sinuous course, repeatedly swerving from right to left and back across the very bow while rolling from side to side. Bow-riders may go along on their sides or even upside down and we have seen individuals proceed while slowly revolving about their long axis. One posture assumed by the bow-rider, which we have only recently noticed, seems of particular significance. This was first observed in *Tursiops* from *Chain* on November 20 and 21, 1958, in the ocean area known as the Blake Plateau. From time to time individuals swimming on their side were seen to throw the tail into a strong downward flexure and hold it in this extreme position for two to four seconds. At these times it was hard to observe the angle of attack of the flukes but it was noticed that such porpoises were generally, if not always, so oriented that the back was towards the long axis of the vessel, that is, a porpoise on the starboard bow coasted on its left side and vice versa. It might be assumed that these animals coast in this posture while belly-down or -up; but this, of course, would be less easily seen from the top of the ship's stem. Wrinkles in the skin were noticed on several occasions when the tail was flexed downwards. These were located at the point of flexure and probably do not have a dynamic significance such as the skin folds reported for this species by Essapian⁶ may have. On May 12, 1959, off Cádiz, Spain, about two dozen *Tursiops* were observed from *Chain*, and tail-down coasting the same as that described above was seen.

On May 16, 1959, just west of the Strait of Gibraltar and on May 26, 1959, in the Malta Channel this activity was observed in *Delphinus*, animals that are for the most part about 6 ft. long. The tail-down coasting posture of *Delphinus* does not appear to differ from that observed in *Tursiops*; however, it has been observed less frequently in *Delphinus* than in *Tursiops*. That is, after first noticing this bow-riding attitude in *Tursiops*, we saw it in the next two encounters with *Tursiops* but only in two of the next eight meetings with *Delphinus*. Since *Delphinus* is in general smaller and of quicker movement than *Tursiops*, the details of its motion may be more difficult to discern; on the other hand, it may assume this particular posture less frequently. Furthermore, varying states of the sea and the heading of the ship relative to the sea probably affect the behaviour of the animals. In neither species can this activity be described as continuous. Individuals can be watched for periods of many seconds riding close to the ship's bow, but assuming the tail-down attitude only at irregular intervals and then for only a few seconds at a time. On August 27, 1960, tail-down coasting was observed in an unidentified species of the genus *Stenella* from *Bear* near 38° 30' N., 78° 00' W. It was noted on this occasion in a porpoise riding on its side at a depth of 5 or 6 ft. in the deeper of two layers of bow-riding animals.

It is readily apparent that some of the observations reported above are not compatible with the bow-riding model proposed by Hayes³. The propulsive force required by the porpoise depends in that case on the magnitude of the angle θ between the streamline and the horizontal (Fig. 1). As this angle decreases exponentially with depth, the explanation offered by Hayes is clearly incomplete when the porpoise is not located in the immediate vicinity of the surface and when small and relatively slow vessels are involved that do not produce bow waves of sufficient size for wave-riding, that is, waves of slopes of 15° or more and large enough to contain the body of the porpoise. It should be pointed out, however, that hydrodynamically, Hayes's explanation, while limited in scope, appears to be correct and that the contradictory data reported by Scholander⁴ seem to be the consequence of limitations pertaining to the latter's apparatus, which did not permit him to control and maintain the position and orientation of the model relative to the wave surface.

Considering next the model proposed by Scholander⁴, one can determine readily that a propulsive force of sufficient magnitude can result when the animal places its tail flukes in a bow wave in the manner shown in Fig. 2. However, the objection raised by Hayes⁷, that the forces and moments do not balance and that consequently the porpoise is not in equilibrium, appears to be sound. Indeed our calculations show that in Scholander's model equilibrium is not attainable: the force on the tail flukes contributes a large moment around the centre of mass and because of the shape of the porpoise and the fact that the pectoral fins are located too near the centre of mass (maximum girth is at the point of insertion of the pectoral fins) it seems impossible that the animal could generate an opposing moment of equal magnitude.

In order to arrive at a model which is consistent with our observations it is proposed to focus attention on the pressure distribution in a horizontal plane ahead of the bow. If one neglects the effect of the

Fig. 3. Pressure distribution in a two-dimensional flow past cylindrical shapes. A, ship's water-line profile; B, circular cylinder; p , pressure at point X; p_{∞} , pressure at a great distance from profile; ρ , density of water; U , velocity of flow

surface and keel, that is, considers the flow to be two-dimensional, one can readily determine the pressure field ahead of the bow with the aid of potential theory. Fig. 3 shows the pressure distribution along the centre-line ahead of the bow, obtained in this manner, for a cylinder having a cross-section of the shape of an ordinary ship's water line as taken from ref. 8. For the sake of comparison the distribution for a cylinder with a circular cross-section is also shown. A streamlined body placed in this region experiences a force which is approximately equal to the negative of the average pressure gradient in the field times the volume of the body⁹. It is apparent from the pressure distribution in Fig. 3 that this force is maximum at the bow and decreases gradually as the distance between the bow and the object increases. At a location where the force due to the pressure field equals the drag experienced by the body from the flow around it, the conditions appear to be right for bow-riding. This situation was considered using the dimensions and shape of a female *Stenella styx* which was harpooned from *Bear* on July 27, 1959, at 37° 42' N., 73° 34' W.¹⁰. The resulting curves are presented in Fig. 4 showing the distance d between the bow and the tail of the porpoise as a function of the length L of the vessel for the water-line profile used in preparing Fig. 3. It should, of course, be understood that the distances shown in the

Fig. 4. Dependence of distance between tail of bow-riding porpoise and the bow on length of vessel for various values of the drag. Drag $D = 1/2 \rho U^2 A C_D$; A , frontal area of porpoise; C_D , drag coefficient

figure are larger than one would expect and that this is due primarily to the assumption of two-dimensional flow. Furthermore, it should be pointed out that it is within the power of the porpoise to vary the distance by appropriate changes in posture that will influence its drag, and that the presence of vertical and lateral pressure gradients in addition to those along the centre-line will make it necessary for the porpoise to assume some of the curious positions that have been described above. These positions remind us of the attitude assumed by the sausage-like object employed by G. I. Taylor⁸ to demonstrate the equilibrium position of a body in a flow field in which the streamlines are curved. In reading Dr. Taylor's paper it becomes clear that, due to the complexity of the situation, intuition will be of little help in arriving at the posture and position the porpoise must assume in order to remain motionless in the pressure field ahead of the bow.

In turning sharply on to the ship's heading for bow-riding in the manner described earlier the porpoise could, of course, be guided visually or by echo-location, but it seems most plausible that in manoeuvring into bow-riding position and during the bow-riding itself, the animal is responding directly in a tactile way to the pressure field generated by the vessel.

In viewing our results it is of course necessary to realize that the situation to which our calculations pertain is a highly stylized one. In reality the porpoises are now coasting, now swimming to make adjustments in their position relative to the ship or to change their posture, now coasting again. These changes seem to be necessary to counteract fluctuations of the pressure field due to the state of the sea and the resultant motions of the ship, and to correct any mismatch between propulsive force and drag occurring, at times, as the result of a change in the animal's posture. The resulting picture is quite involved, and a more complete and accurate analysis of the bow-riding activity would require detailed information regarding the shapes assumed by the animal and the field of flow ahead of the vessel.

Recently, near 38° 30' N., 73° 00' W. on August 26, 1960, we observed what appeared to be the riding of wind waves five to six feet high by a porpoise of the genus *Stenella* the length of which was about 6 ft. In the best-observed instance two porpoises rode side by side in exactly the same posture for several seconds near the top of the forward slope of the wave. Little, if any, of the porpoises' bodies were exposed (possibly the dorsal fins). The heads were down and the tail portions were raised but seemingly not quite to the extent that the long axes of the bodies were parallel to the forward slope of the wave. After proceeding with the wave for several seconds the porpoises fell behind it. This observation is similar to those recently reported by Caldwell and Fields¹¹ of 'surf-riding' porpoises. They report that the animals rode the top front of the wave with their heads down and only their dorsal fins and a small part of their backs exposed. In these cases Hayes's model is not only appropriate but it seems to be the only feasible one. Our calculations show that even shallow wind waves having slopes of 10–18° and travelling at velocities in the vicinity of 5–6 m./sec. could be utilized for this purpose by porpoises in minimum drag posture; and based on this observation it seems not unreasonable to conclude with the speculation that in regions of the oceans where steady, strong winds are known to raise large waves that move steadily over long distances,

even large cetaceans could very well use wave-riding techniques for migratory travel.

RADIOCAESIUM IN HUMAN BEINGS

By DR. J. RUNDO

Atomic Energy Research Establishment, Harwell

THE detection of the long-lived fission product, caesium-137, in human beings in the United States in 1955¹, was confirmed for residents of the United Kingdom in 1956 at Harwell² and at Leeds³. Subsequent measurements of body radioactivity made at the Atomic Energy Research Establishment, Harwell, have demonstrated the presence of radiocaesium in all persons, whether employed at Harwell or not. The results of measurements made in 1956 and 1957 were reported in 1958⁴; a re-examination of all the early measurements has now been made, and some conclusions about the trend of the levels to the end of June 1960 are presented here.

A description of the method of measurement has been given previously^{4,5} and will not be repeated here, but it should be mentioned that in comparing the levels from subject to subject it is convenient to use the ratio of caesium-137 content to potassium content. In this way the effects of variations in the sizes of the subjects and in their potassium contents are minimized, and the caesium content is related to the mass of the muscle, its main site of deposition. In the following results the caesium-potassium ratio is expressed in $\mu\text{c. caesium-137 per gm. potassium}$.

Results

(a) Subjects Resident near Harwell

The data for subjects living in Berkshire and Oxfordshire are presented in Table 1, where the mean values for six-monthly periods to June 1959, are given; since June 1959, measurements have been made in the months shown. Most of these persons are employed at the Atomic Energy Research Establishment, Harwell; none has had any occupational exposure to caesium-137. In Fig. 1 the trends with time are shown for some individuals who have been measured more than once. In considering the significance of the difference between the mean values for any two consecutive periods, and of small (10 per cent) variations in the results for any one individual, it should be borne in mind that the standard error of counting is at least $\pm 4 \mu\text{c. caesium-137 per gm. potassium}$, and that the groups being averaged are small. Further, up to December 1958, the groups were largely composed of different subjects, and the justification for the comparison of the mean values from those different groups is open to question. Also, the inclusion

Table 1. MEAN CAESIUM-POTASSIUM RATIOS FOR SUBJECTS RESIDENT IN BERKSHIRE AND OXFORDSHIRE

Period	No. of subjects	$\mu\text{c. Caesium-137 per gm. potassium}$

Jan.-June 1959	12	56
July 1959	11 (12)	63 (66)
Dec. 1959	7 (8)	56 (61)
Mar. 1960	10 (11)	58 (62)
June 1960	10 (11)	52 (55)

of one extreme value has a pronounced effect on the mean for the group; one subject who has only been measured regularly since July 1959 is in this category, and in Table 1 the mean values in parentheses are those including this man. Apparently, the caesium-levels in these subjects remained substantially constant until about the middle of 1957, after which they increased to a maximum in July 1959. The mean value for June 1960 shows a significant fall from the December 1959-March 1960 values.

(b) Subjects Resident near Windscale

The accidental release of radioactivity from the No. 1 Pile at Windscale in October 1957 led to temporary increases in the radiocaesium content of milk from a wide area of England and Wales⁶⁻⁸; the biggest increases were close to Windscale⁶. Although no extensive study has been made of the levels in humans in this area, a few subjects have been measured, and the results in Table 2 illustrate the effect of the accident. The pre-accident level was $107 \mu\text{c. caesium-137 per gm. potassium}$ (mean for four subjects); this was 2.5-3.0 times the contem-

* These two men left Windscale on 10.1.58; their caesium-137/potassium ratios on that date would have been somewhat higher than the values in the table.

porary average for subjects resident in Berkshire and Oxfordshire. This can be attributed in part to the higher rainfall in the area around Windscale with the resulting higher caesium-137 levels in milk³, and in part to slight environmental contamination from the Windscale Works⁴. For this reason the level cannot be regarded as typical for northern England. The caesium-137/potassium ratio increased roughly four-fold to a maximum around January-March 1958 as a result of the accident, and the level fell to less than twice the pre-accident value towards the end of 1958 (c) Other Subjects

Only a few subjects resident elsewhere have been measured; the results are given in Table 3, in chronological order.

There is a general increase in the levels during 1956-59, but the data are too sparse for any definite conclusions to be drawn or correlations to be made (for example, with levels in milk). However, it is interesting to note that, with one exception, all subjects measured in 1957, 1958 and 1959 gave values higher than the means in the corresponding periods for persons living in Berkshire and Oxfordshire.

Correlation with Milk Intake

It is known⁵ that cow's milk is an important source of caesium-137 in humans, and a correlation might be expected to exist between the caesium-potassium

ratio in humans and their daily milk consumption. The latter quantity is somewhat difficult to determine and is likely to vary from day to day. However, data on nine subjects resident near Harwell, whose milk intakes were considered to be reasonably constant and to be known, were used. It should be noted that in estimating the milk intake of the nine subjects an attempt was made to include an allowance for milk used in cooking, but not for that in a variety of manufactured foods which are of widespread distribution throughout the country. In Fig. 2 the caesium-137/potassium ratios (measured in late 1958 or early 1959) are plotted as a function of daily milk intake; two subjects drinking 0.43 litre per day both had 46 $\mu\text{C. caesium-137 per gm. potassium}$. There is apparently a correlation between the caesium-137/potassium ratio *in vivo* and the milk intake, and it suggests that at that time about 26 $\mu\text{C. caesium-137 per gm. potassium}$ originated from sources other than milk. The mean value for all control subjects was 56 $\mu\text{C. caesium-137 per gm. potassium}$, so that milk was responsible for about one-half the average caesium burden.

Fig. 2. Correlation of caesium-137/potassium ratios *in vivo* with daily milk consumption

When the caesium-137 concentration (in $\mu\text{C. per kgm. body-weight}$) was plotted as a function of daily milk intake, a similar correlation was found but with greater scatter. Since for equal body-weights the musculature can vary considerably, and since the greater part of the body's content of potassium and caesium is in muscle, this is not altogether surprising.

Radiation Dosage from Potassium and Caesium-137

The radiation dosage to the gonads may be calculated if we assume that the potassium and caesium-137 are uniformly distributed throughout the body. There is evidence that the potassium content of gonadal tissue is close to 0.20 per cent by weight¹⁰, which is about the same as the average for the whole body (0.21 per cent by weight¹¹). There are no data on the distribution of caesium-137 in individual tissues, but there seems to be no *a priori* reason to suppose that it differs markedly from potassium, and we shall incur no great error in the assumption of uniform distribution.

Taking published values for the β -particle and γ -ray emissions of potassium^{12,13}, and deriving a value for the 'geometrical factor' for the γ -ray contribution from the calculations of Bush¹³, with the application of the theorem of reciprocal relations¹⁴, the dose-rates to the testes from 0.2 per cent by weight of

potassium become 17 and 2 mrad per year from β -particles and γ -rays respectively. These are in agreement with the values of 18 and 2 mrad per year calculated by Spiers¹⁰, who used a value of 0.215 per cent for the mean potassium content of the body.

For the mean value of 63 μCi caesium-137 per gm. potassium (July 1959), the dose-rates from the radiocaesium are 0.53 and 0.56 mrad per year from β -particles and γ -rays respectively, it being assumed that the mean β -particle energy is 0.227 MeV.¹¹ The total dose-rate to the testes is thus 1.1 mrad per year from caesium-137 compared with 19 mrad per year from potassium, an increase of about 6 per cent. Compared with the total background radiation of approximately 100 mrad per year, the increase is about 1 per cent.

This calculation was made with the assumption that the metastable barium-137m was in equilibrium with its parent caesium-137 in the gonadal tissue. The metabolic dissociation of barium-137m from its parent in various tissues of the rat, reported recently¹², would have only a slight effect on the calculated dose-rates. No dissociation of barium-137m was observed in the testes, but there was an excess of barium-137m in the blood. If this also applies in man, the β -particle dose-rate to the testes would be increased very slightly by the electrons from the internally converted γ -rays from the excess barium-137m in the blood present in the gonad, while the γ -ray dose-rate would not be altered significantly.

Discussion

Since the caesium-137 content of an individual varies with the milk intake, and the concentration of radiocaesium in milk varies with geographical location⁸, a comparison of the mean values *in vivo* with those obtained elsewhere is scarcely justifiable. However, it is of interest to compare the trend observed in the groups resident in Berkshire and Oxfordshire with the trends observed in the United States at the Argonne National Laboratory, Illinois, and at the Los Alamos Scientific Laboratory, New Mexico. At the former laboratory, Miller and Marinelli^{17,18} have published the mean caesium-137/potassium ratios in a group of eight to thirteen control subjects; these are set out in column two of Table 4. At Los Alamos results for control groups of 10 subjects measured in 1958, 14 subjects measured in 1957 and 37 subjects measured in 1958 have been reported¹⁹⁻²¹ and these are included in column three of Table 4. The 1956 results are taken from Fig. 3 of ref. 19, the 1957 results are taken from Fig. 2 of ref. 20, while the 1958 results are for the 19 subjects who were measured in both the first and second halves of the year²¹. The data show that not only is the trend reported for Chicago substantially the same as that found in Britain, but the mean values are practically identical. The values reported from Los Alamos are very similar for 1956 and 1957, but are somewhat higher for 1958. However, Langham and Anderson²² reported a mean value of 50 μCi caesium-137 per gm. potassium in 500 residents of New Mexico for the whole of 1958.

We may conclude that the radiocaesium found in persons employed at the Atomic Energy Research Establishment, Harwell, is a consequence of world-wide fall-out from nuclear test explosions, rather than of local contamination. Some support for this conclusion may be seen in the fact that the subject

Table 4. MEAN CAESIUM-137/POTASSIUM RATIOS (IN μCi PER GM.) IN CONTROL GROUPS RESIDENT IN ILLINOIS AND IN NEW MEXICO (U.S.A.) AND IN BERKSHIRE AND OXFORDSHIRE (U.K.), RESPECTIVELY

Date	Chicago, Illinois	Los Alamos, New Mexico	Berkshire and Oxfordshire
Jan.-June 1956	32	} ~32	33

drinking two pints of milk daily, and with a content of 73 μCi caesium-137 per gm. potassium (Fig. 2) has never had any contact with radioactive material and only visited Harwell once, for the purpose of the estimation of his body content. Comparison of the mean values for all control subjects (as set out in Table 1 and plotted in Fig. 1) with either the rate of fall-out or the cumulative fall-out^{23,24} at Abingdon, Berkshire, does not enable us to attribute the increase observed during 1956-59 in the levels *in vivo* to either of these parameters exclusively. However, it is clear that the decrease from the maximum level in July 1959 must be associated with the reduction in the rate of fall-out since the spring of that year²⁵.

With regard to the correlation between the caesium-137/potassium ratio and the milk intake, it should be noted that there is a correlation between milk and meat consumptions which has an economic basis. Since meat contains caesium-137, a correlation might still be found as shown in Fig. 2, even if there were no caesium-137 in milk. For the nine subjects from whom the data in Fig. 2 were obtained there were no major differences in economic backgrounds; but the possibility should be borne in mind.

A correlation between the caesium-137/potassium ratio *in vivo* and the daily milk consumption was also found by McNeill and Green²⁶ for 30 subjects in Toronto, Canada. The mean content was 51 μCi caesium-137 per gm. potassium in December 1958, which is about the same as found in Britain. Anderson²⁰ plotted the mean caesium-137/potassium ratios *in vivo* in 1957 for different regions of the United States against the caesium-137/potassium ratios in the milk in those regions and demonstrated a correlation; extrapolation to zero indicated that 23 μCi caesium-137 per gm. potassium derived from food other than milk. This is similar to the value of 26 μCi caesium-137 per gm. potassium deduced from Fig. 2. However, it should be noted that there are substantial differences between the average diets of residents of the United Kingdom and of the United States.

It is not clear to what extent the levels of caesium-137 *in vivo* are controlled by the daily potassium intake, and the possible influence of naturally occurring (inactive) caesium-133 is also unknown. That the metabolisms of caesium and potassium are not identical is shown by the fact that the value of the ratio:

$$\frac{\mu\text{Ci } ^{137}\text{Cs per gm. K in vivo}}{\mu\text{Ci } ^{137}\text{Cs per gm. K in urine}}$$

in three subjects studied by Miller and Marinelli¹⁷ in 1956 and 1957 when the caesium-137/potassium ratios *in vivo* were essentially constant, averaged 2.2. A value of 1.95 was found in one subject tested by

me in early 1959 when the levels *in vivo* were increasing, and a value of about 2 for the dietary discrimination factor was estimated by Langham and Anderson²².

I am indebted to Mr. R. G. Speight for assistance in many of the measurements reported.

Note added in proof. The decrease from March 1960 of the mean caesium-137/potassium ratio *in vivo* has been maintained. In September the value for 13 subjects resident in Berkshire and Oxfordshire was 48 μCi caesium-137 per gm. potassium (cf. Table 1).

OBITUARIES

Prof. H. W. Swift

HERBERT WALKER SWIFT, emeritus professor of engineering in the University of Sheffield, died near Keswick on October 14. He was born in 1894. From elementary school he won a scholarship to Christ's Hospital and from there an open scholarship to St. John's College, Cambridge, where he read mathematics and physics. He served in the First World War, rising to the rank of captain, and was wounded and mentioned in despatches. After the War he returned to Cambridge and completed the Mechanical Science Tripos as a prizeman with first-class honours and he also won a 'half-blue' for swimming.

Swift obtained his early engineering experience with Hollins Brothers, where he became chief engineer. In 1922 he was appointed assistant lecturer in the University of Leeds. By 1926 he had published papers on several diverse topics and was awarded a D.Sc. by the University of London. For ten years he was head of the Mechanical Engineering Department at Bradford Technical College, and continued to publish in the field of power transmission and lubrication.

In 1936 Dr. Swift was appointed to the chair of engineering in the University of Sheffield, which chair then embraced the Civil, Mechanical and Electrical Departments of the University. During his period at Sheffield he was induced to take a scientific interest in the plastic forming of metal in all manner of forming processes. At a time of empiricism in this field, he made a remarkable impact in bringing logical and scientific thought to the problems involved and was the instigator of a school of plasticity which has had far-reaching subsequent influence through the work of his students.

He was responsible for the planning of both buildings and courses in the enlargement of the School of Engineering at the University of Sheffield. His ill-health brought about his premature retirement just before this task was complete.

Swift was a man of immense energy, deep insight, great enthusiasm and great kindness. He was brilliant, thorough and never mediocre. He had an unquenchable thirst for knowledge. In addition, his students will remember him as a vigorous and inspiring teacher with a readiness to appreciate their personal problems and treat them sympathetically.

J. P. DUNCAN

Dr. H. Zeitlinger

HEINRICH ZEITLINGER joined the firm of Henry Sotheran and Co. in 1894; save for a short break, he remained with it until his death on October 15, in his ninetieth year. A bookseller of distinction, he rendered notable service to science.

The volumes of Sotheran's "Bibliotheca Chemico-Mathematica" were, according to the original title-page, "compiled and annotated by H. Z[eitlinger] and H. C. S[otheran]", and on them Zeitlinger lavished the affection and erudition of the true bibliophile. Almost every famous work on the exact sciences is listed, with comments identifying and characterizing the author, indicating the content, and illuminating the treatment by apt quotation from a wide variety of authorities. An austere bibliographer might wish that these quotations had been dated, since this would have helped in tracing changes in critical estimation, but the defect is slight in such a wealth of scholarship spiced with gentle humour. Where else, for example, can one hope to learn of the only mathematical treatise written to alleviate the pangs of sciatica?

Zeitlinger's expert knowledge of Newton's work enabled him to gather together a considerable portion of Newton's library, which had been lost to sight for some two hundred years and partly dispersed. Several valuable items were recognized from annotations in Newton's handwriting, which Zeitlinger had studied with much care. It was thus possible, for

example, to identify Newton's own copy of Barrow's "Euclid", and first and second editions of the "Principia" with his manuscript revisions and additions. The collection was purchased by the Pilgrim Trust and presented to Trinity College, Cambridge, in

the library of which it now rests; but for Zeitlinger's detective skill, scholarly enthusiasm and admiration for Newton, the opportunity of assembling this historic collection might have vanished for ever.

T. A. A. BROADBENT

NEWS and VIEWS

Meteorological Office: Headquarters Reorganization

THE present structure of the Meteorological Office was set up in 1957 as a result of the recommendations of the Brabazon Committee. The forthcoming move of the headquarters sections of the Office, now divided between London, Harrow and Dunstable, to Bracknell during 1961 has provided an opportunity to reconsider that organization in the light of changes which have taken place, and are likely to take place in the future, in meteorology. The division of the Office into two directorates, for services and for research, respectively, with an administrative division controlled by an assistant secretary, will remain unchanged. The balance between the research and services directorates has been improved by the creation of a new deputy director post, which has been filled by Mr. J. S. Sawyer, formerly chief forecasting research officer. He will be deputy director (dynamical research), in charge of climatological research in addition to dynamical and synoptic research. This reflects the view that forecasting work should be closely integrated with climatological investigations. The importance of the relation between the latter and long-range forecasting, in particular, is emphasized by the transfer of long-range forecasting research from the synoptic research to the climatological research branch.

Two aspects of the work of the directorate of services have increased greatly in importance since 1957. One is the rapid growth of public services, and this is catered for by the creation of an assistant director (general services) post, whose main concern will be agricultural services and the Weather Information Centres. The Climatological Services Branch will now be responsible for all climatological inquiries of a routine nature, including world climatology and marine climatology (formerly dealt with by the Climatological Research and Marine Meteorology Branches, respectively). The second development is the increasing complexity of the problems of data processing, and a new post, assistant director (support services), has been created to deal with these problems. The creation of the new branch will facilitate the development of an integrated system of data collection, processing and storage, a problem which has been the subject of much intensive work in the Office during the past few years.

Dr. J. M. Stagg, C.B., O.B.E.

ON September 7, Dr. J. M. Stagg retired from his position as director of services of the Meteorological Office. Dr. Stagg, who comes from Dalkeith, Midlothian, joined the Meteorological Office in 1926, and during 1932-33 led the highly successful British Polar Year Expedition to Fort Rae in Canada. His name soon became well known among geophysicists, and in 1939 he was appointed superintendent of Kew Observatory, where he carried out some notable work

in radiation. In 1943, Dr. Stagg was made chief meteorological adviser to the Supreme Commander, Allied Forces, Europe, and it was he who briefed General Eisenhower in preparation for the D-day landings in Normandy in 1944. For his war-time services Dr. Stagg was made an Officer of the Legion of Merit by the President of the United States. After the War, Dr. Stagg was made principal deputy director of the Meteorological Office, and in 1957 he was appointed to the newly created post of director of services, responsible for the 'operational' side of the Office. His keen physical insight and excellent administrative qualities made him outstandingly successful in this capacity. He was created a C.B. in 1954. In the international field, Dr. Stagg has taken a keen interest in the activities of the International Union of Geodesy and Geophysics, and he was for a time general secretary of that Union. In 1955, he was awarded the Gauss-Weber Medal for his contributions to geomagnetism. It is understood that he intends to resume his work in this field during his retirement.

Dr. A. C. Best, O.B.E.

ON September 8, Dr. A. C. Best succeeded Dr. J. M. Stagg as director of services of the Meteorological Office. After graduating with first-class honours in mathematics and physics at the University College of Wales, Cardiff, Dr. Best joined the Meteorological Office in 1926 as a junior professional assistant. During his career he has had a wide experience of both the research side and the operational side of the Office, at home and abroad. His early work was in the field of atmospheric turbulence, culminating in the publication of an important Geophysical Memoir on the transfer of heat and momentum in the lowest layers of the atmosphere. His later research has been devoted mainly to cloud physics, and he has written a number of papers on the formation and size distribution of raindrops and cloud droplets. He was awarded the L. G. Groves Memorial Prize for Meteorology in 1952, and made O.B.E. in 1953. Since 1955 Dr. Best has been a deputy director on the services side of the Meteorological Office.

Zoology in the University of Delhi:

Prof. B. R. Seshachar

PROF. B. R. SESHACHAR, who has been professor of zoology in the University of Mysore since 1946, has been appointed professor of zoology in the University of Delhi. After a few papers on teleosts, anura and palaeontology, he worked during 1932-45 on *Gymnophiona*, describing new species and investigating their development, their germ cells and their cytology. His discovery of a homologue of Bidder's organ is perhaps not universally known. Since 1946 he has been mainly concerned with ciliate Protozoa. India can probably fill many gaps in our existing knowledge of this group. For example, Seshachar has made a

collection of Indian types of *Spirostomum* sp.; this includes different mating types which can readily be induced to conjugate, whereas this has only rarely been seen in Europe. However, his main work has been on the chemistry and physics of the macro-nucleus. Perhaps Seshachar's greatest service to Indian zoology was to organize a laboratory at Bangalore in which a wide variety of researches went on side by side. Apart from work related to his own, classical comparative morphology and embryology, especially of teleosts, were studied, as were the anatomy and development of *Loris tardigradus*. Endocrinological research was carried out on various Indian vertebrates, and both nuclear and extranuclear cytology were studied in a number of invertebrates. Even when the results of such work are not very novel, it is essential as a foundation for the teaching of physiological zoology in India.

Biology in the University of Malta :

Dr. O. L. Thomas

DR. OWEN LEWIS THOMAS, who has been appointed to the chair of biology in the Royal University of Malta, was born in New Zealand and graduated in medicine at Otago University Medical School. While a lecturer in anatomy in the Department of Prof. W. E. Adams, he gained his M.D. (with distinction) in that subject and was awarded a Beit Memorial Medical Research Fellowship. In 1946, he entered Oriel College, Oxford, and studied under Dr. John R. Baker in the Linacre Department of Zoology and Comparative Anatomy, gaining his D.Phil. degree in biological sciences. In 1951, Dr. Thomas was appointed senior lecturer in physiology in St. Bartholomew's Hospital Medical School, London. His main research publications relate to the histology and cytology of the nervous system. He has recently completed his D.Sc. thesis while acting as a teacher of biology in the Napier Girls' High School.

The National Central Library

THE forty-fourth annual report of the Executive Committee of the National Central Library, covering the year ended February 29, 1960, refers to disappointing progress in planning the proposed new building in Store Street (Pp. 20. London: The National Central Library, 1960). The possibility of obtaining additional storage space outside Central London is being investigated. The lending service of the Library has shown a marked tendency to expand, the number of requests for loans increasing by nearly 8 per cent, although books published since January 1, 1959, are no longer supplied to libraries borrowing through the Regional Library Bureaux. To facilitate quick communication in dealing with urgent requests, telex is being installed at the Library. The Executive has also recommended putting in hand a project involving the use of the xerographic process to deal with the arrears of material awaiting insertion in the National and Outlier Union Catalogue, in which finally the great majority of works available for loan in Britain will be recorded. The work done by the British National Book Centre on behalf of British libraries in re-allocating duplicate and other redundant books is now being extended to overseas libraries. The Executive Committee and the Trustees, after considering the Roberts Report, have reiterated to the Minister of Education their view that the inter-library lending system, with its centre at the National Central Library, should be regarded as a whole and

financed half by the State and half by the participating libraries. The alterations in the Library's book selection policy are also considered (see *Nature*, 187, 992; 1960). The percentage of applications successfully handled decreased from 76.18 per cent in 1958-59 to 72.22 per cent in 1959-60, probably in consequence of the fact that such requests increasingly relate only to books that could not be traced through the Regional Systems. Of the 76,521 separate issues from or through the Library, 12,793 were to university libraries, 8,318 to special outlier libraries, 2,299 to Government departments, 3,622 to overseas libraries, 3,299 to industrial and research organizations, 33,902 to public libraries and 10,323 to adult classes. University libraries lent 28,611 books, and 3,494 books were lent to 53 countries and 1,871 borrowed from 29 countries, the chief borrowers being Hungary (435), West Germany (352), Czechoslovakia (478) and U.S.S.R. (230), and the chief lenders the U.S.S.R. (414), France (380) and West Germany (362).

Rubber and Plastics Research Association of Great Britain

THE Articles of a new combined rubber and plastics research association for the United Kingdom—to be known as the Rubber and Plastics Research Association of Great Britain—were adopted at an extraordinary general meeting of the executive committee of the Research Association of British Rubber Manufacturers in London on November 15. Seventy members of the British Plastics Federation, about a third of its membership, have already agreed to support the new Association. Speaking at the meeting, Mr. P. W. Howard, president of the Research Association of British Rubber Manufacturers, pointed out that the Research Association of British Rubber Manufacturers was engaged on work of overlapping scientific and technological interest to the rubber and plastics industries, and also on work in the thermoplastics field, much of which was of a similar nature to that envisaged by the plastics industry. The plastics manufacturers who are founder-members will be represented in the Association by a Plastics Research Committee and by representatives on the Council. They become members of the new Association as from January 1, 1961. Both industries will gain much from this joint venture. It has been announced by Mr. David Radford, chairman of the British Plastics Federation, that research will be carried out at the existing laboratories of the rubber industry, at Shawbury, near Shrewsbury, and that work has already begun on new buildings, with an area of 14,000 sq. ft., to house the additional personnel and equipment for plastics research.

Computer Centre at Woolwich Polytechnic

SIR THOMAS SPENCER, chairman of Standard Telephones and Cables, Ltd., and a governor of Woolwich Polytechnic, opened the Computer Service Centre at the Woolwich Polytechnic on November 22. The Centre has a *Stantec Zebra* automatic electronic digital computer, designed by Dr. W. L. van der Poel, of the Netherlands Post Office Research Laboratories, and developed and manufactured by Standard Telephones and Cables, Ltd. The machine is suitable for mathematical, scientific, engineering and statistical calculations and for commercial, financial and industrial applications. A large library of problems already programmed is available to users. The Computer Centre, which is established in the

Mathematics Department of the Polytechnic, will be used for the following purposes: (1) as a service to users in industry and commerce who are invited to discuss their problems with the computer staff and use time on the computer; a fee will be charged for this latter service; (2) for the training of students in the use of digital computers. It is intended that every student of the Polytechnic who is studying for a B.Sc. degree in mathematics, physics, chemistry, engineering or economics, and every student studying for a diploma in technology or a higher national certificate with endorsements, will have an opportunity to write programmes for and to operate the computer; (3) as an aid to research by members of the staff and postgraduate students of the Polytechnic and other educational establishments.

Liverpool Observatory and Tidal Institute

THE Liverpool Observatory and Tidal Institute, which for many years has been administered jointly by the Mersey Docks and Harbour Board and the University of Liverpool, is to become the sole responsibility of the University. The Observatory was founded in 1845 by the Liverpool Dock Trustees, and the Mersey Docks and Harbour Board, on its formation in 1858, took over the operation of the Observatory. The main reason for its establishment was the absence of knowledge at that time concerning nautical astronomy and even the most elementary details of correct determination of chronometer-rates and meteorology. The present Observatory building at Bidston was erected in 1864. The Observatory continued largely as an astronomical and meteorological institution until the death in 1928 of the then director, Mr. Plummer, an officer of the Mersey Docks and Harbour Board. For some years prior to this there had been close association with the Tidal Institute which had been founded by the University of Liverpool, largely through the influence of the late Mr. Charles Booth, a Liverpool shipowner, with whom was associated Prof. J. Proudman, and from January 1, 1929, the Board and the University agreed to combine the tidal work of the Institute and the work of the Observatory at Bidston under the name "The Liverpool Observatory and Tidal Institute", administered by a joint committee of both bodies. Since that time the joint committee has been extended to include representatives of the Admiralty and the National Institute of Oceanography. In addition to the work of tidal prediction, for which it is famous, the Institute has built up an international reputation in the scientific world and is deeply involved in the study of major problems such as the determination of mean sea-level and the investigating of storm surges as well as other matters involving geophysics and oceanography. The activities of the Institute are now far wider than was envisaged when the joint committee was set up in 1929, so the Dock Board has handed over its responsibilities to the University of Liverpool. For the time being the Observatory will be administered by the acting director, Dr. J. R. Rossiter, following the retirement of Dr. A. T. Doodson (see *Nature*, November 19, p. 625).

The Netherlands Universities Foundation for International Co-operation

THE organization known as the Netherlands Universities Foundation for International Co-operation was founded in 1952 to promote international

co-operation in academic life at universities and elsewhere. It seeks to do this by functioning as a centre for consultations among institutes and persons at home and abroad; by encouraging the founding and maintaining of special forms of international education in the Netherlands; by keeping those abroad informed about university life and scientific activity in the Netherlands and vice versa; and by lending more general assistance with regard to measures and facilities on behalf of international academic and scientific contact and exchange. The Board of Governors is composed of representatives of all Dutch universities and the honorary president is H.R.H. The Prince of the Netherlands. The Foundation furthers international cultural exchanges in various ways, among others by founding institutions and courses of education on an international basis. Here it is active in a field which has been reconnoitred inadequately, and which presents many problems. It is aware of the need to subject this field of activity to further investigation. As yet, only a modest beginning has been made on this work, but individual research workers have been given commissions to form teams of experts to study comparative education; the problems of inter-cultural communications; the difficulties students from abroad encounter in adapting themselves in the Netherlands; and the evaluation of study in a foreign country. Another subject receiving close attention is European integration, the gradual achievement of which is believed to depend to a considerable extent on voluntary international co-operation within the world of higher education and research, and on the attention given to European affairs in individual institutions of higher learning. A pamphlet prepared by the Foundation describes the detailed work of the organization (Netherlands Universities Foundation for International Co-operation (NUFFIC): Aims and Activities. Pp. 16. The Hague: Netherlands Universities Foundation for International Co-operation, 1960).

The Mauritius Institute

THE annual report of the Mauritius Institute for 1958 notes the increasing demand on the library services, which include a scientific section, which has been combined with the Library of the Royal Society of Arts and Sciences to form a nucleus of works on natural history and biology (Pp. i + 27. Port Louis: Mauritius Institute, 1959. 25 cents). The report includes brief descriptions of the various sections of the Natural History Museum of Port Louis, which was reopened to the public in 1957, as well as of the Historical Museum. A function of the Mauritius Institute is to build regional collections and have them accurately identified, and the annual reports of the Institute should be particularly useful to workers on any group of the Mascarene fauna or flora. This Museum report includes some notes on research in zoology, entomology and botany, a list of publications during the year and also lists of Museum accessions, additions to the fauna of the Mascarene Islands and of library acquisitions. Similar lists are given in the annual report of the Mauritius Institute for 1959, to which are also appended a note on recent advances in the study of the fauna of the Mascarene Islands and one on the Special Collection of the Mauritius Institute Library dealing with the Mascarenes, Madagascar and the Indian Ocean (Pp. ii + 28. Port Louis: Mauritius Institute, 1960. 50 cents).

Public Health and Medicine In the U.S.S.R.

THE World Health Organization has issued a useful introductory guide to published material on public health and medicine in the U.S.S.R., based mainly on the holdings of the libraries of the World Health Organization and of the United Nations in Geneva (*Library News*, 13, Supp. No. 2. Pp. 130. Geneva: World Health Organization, 1960). Works published during 1946-60 are included, but the emphasis is on those published since 1954, and on translations, surveys, etc., chiefly in English and French. The material is arranged under nine sections: guides to Soviet medical and scientific publications; periodicals (including a list of cover-to-cover translation journals); abstracting and indexing periodicals; bibliographies; directories; dictionaries and encyclopædies; administrative material; surveys; and miscellaneous material. The section dealing with administrative material is limited to publications issued in the U.S.S.R.; in the remaining sections works published in the U.S.S.R. and works published outside the U.S.S.R. are listed separately. Most of the entries are annotated and there is an alphabetical index.

U.S. Scientific Programmes In the Antarctic

THE September issue of the *IGY Bulletin*, published by the National Academy of Sciences, provides a review of the status of the United States scientific programmes in the Antarctic, including many results of the International Geophysical Year and subsequent investigations, as well as descriptions of programmes in progress at the moment. The report contains contour maps showing the thickness of the Antarctic ice-cap and surface elevations; a description of the *Echo I* communications satellite, and of the long-range communications experiment for which it was designed as a 'passive' reflector of radio signals; and a summary of solar activity, geomagnetic disturbances, and decisions of the World Warning Agency during International Geophysical Co-operation 1959, just past the peak of sunspot activity reached during the International Geophysical Year; the relationship of solar activity and its associated terrestrial effects during the International Geophysical Co-operation 59 period to the 11-year-old solar-cycle is also described.

Automatic Data-processing In University Administration

EACH year all the students admitted to King's College, Newcastle upon Tyne, are required to register before they start their work. The registration procedure involves the completion of a number of forms giving particulars about the student's date of birth, grant-giving body if any, place of residence, both while at home and at University, which out of a large range of courses he is intending to take, whether he is a new or returning student, an undergraduate or a graduate, and similar information to enable the University administration to have a complete record of the student, to arrange lecture room accommodation and to prepare the statistics required by various bodies. When done by hand this work occupies clerical staff for approximately one term. This year the task has been performed on the automatic digital computer in the University of Durham Computing Laboratory. The information on the forms was transferred to punched paper tape and processed on the computer. In just over two days

all the lists and statistics required were produced, and the final lists distributed one week after the start of term. Further information about the tasks performed may be obtained from the Director, University Computer Laboratory, 1 Kensington Terrace, Newcastle upon Tyne, 2.

The Ecological Society of Australia

THE Ecological Society of Australia was inaugurated at a meeting of plant and animal ecologists held in Canberra on August 1. The objects of the Society are similar to those of the corresponding bodies in Great Britain and the United States. They include promotion of ecological research and the publication of the results of research, facilitation of exchange of ideas among ecologists working in different fields, and encouragement of the practical application of ecological principles. Management of the affairs of the Society is vested in a Council, of which the executive officers for the current financial year are: *President*, Dr. K. H. L. Key; *Secretary*, Mr. J. H. Calaby; *Treasurer*, Mr. A. G. McArthur. The constitution provides for the annual general meeting to be held in the month of August, with a further general meeting in association with each meeting of the Australian and New Zealand Association for the Advancement of Science; additional meetings may be called at the discretion of the Council. The subscription for the current year has been set at £1. The address of the Secretary is: c/o Wildlife Section, Commonwealth Scientific and Industrial Research Organization, P.O. Box 109, Canberra.

The Institute of Physics and Physical Society: Awards

THE Council of the Institute of Physics and the Physical Society has made the following awards: *Duddell Medal*, to Dr. J. B. Adams, director-general of C.E.R.N. (European Organization for Nuclear Research), for his leadership of that team; *Charles Vernon Boys Prize*, to Prof. A. W. Merrison, University of Liverpool, for his distinguished research in experimental physics; *Charles Chree Medal and Prize*, to Dr. S. E. Forbush, of the Carnegie Institution of Washington, for his distinguished work on cosmic radiation. The following appointments have also been made: *Guthrie Lecturer*, Dr. D. Shoenberg, of the Royal Society Mond Laboratory, Cambridge, to be Guthrie Lecturer for 1961; *Thomas Young Orator*, Dr. H. H. Hopkins, of the Imperial College of Science and Technology, to deliver the Thomas Young Oration in 1961.

Royal Society: Awards

Rutherford Memorial Appointment. Under the terms of the scheme to commemorate the late Lord Rutherford of Nelson the Council of the Royal Society has appointed Mr. W. J. Darcey (University of Melbourne) to be Rutherford Scholar for 1960 for three years, to carry out research in experimental nuclear physics at the Clarendon Laboratory, Oxford.

Paul Instrument Fund. Awards of grants by the Paul Instrument Fund Committee have been made as follows: £1,400 per annum for two years, in supplement of a previous grant, to Prof. G. F. J. Garlick, Department of Physics, University of Hull, for the continuation of work on solid state light image amplifiers; £2,000 in supplement of a previous grant, to Prof. D. Gabor, professor of applied electron physics at the Imperial College of Science and

Technology, and Dr. D. Jones, for additional equipment for use in connexion with the development of an electron interference microscope; £1,000 in supplement of a previous grant, to Dr. H. B. Barlow, assistant director of research, department of physiology, University of Cambridge, and Mr. P. E. K. Donaldson, technical officer, Physiological Laboratory, University of Cambridge, for further work on the development of (a) a device for automatically improving coding of messages, and (b) a diffused storage sequence engine.

The Pugwash International Conferences of Scientists

THE next two conferences in the series of Pugwash International Conferences of Scientists will be held in Moscow during November 27–December 4, and in the United States in the summer of 1961. The subject of both conferences will be "Disarmament and World Security", which will be discussed under two headings: (a) problems of disarmament and arms control; and (b) the role of scientists in the creation of a stable and peaceful world. About sixty-five scientists from a dozen countries will take part in the Moscow conference, the largest national groups being from the United States and the U.S.S.R. During their stay in Moscow, the participants will be the guests of the Soviet Academy of Sciences. The proceedings of the conference will be private, but a statement will be issued at the end. Further information can be obtained from Wayland Young, 100 Bayswater Road, London, W.2.

The Australian Mathematical Society: Summer Research Institute

THE Australian Mathematical Society has decided to hold its first Summer Research Institute at the Australian National University, Canberra, during January 3–31, 1961. Prof. T. M. Cherry (University of Melbourne) is to be the first director of the Institute, and will be assisted by Drs. H. Levey and J. Gani (University of Western Australia) as secretaries. The Australian National University has agreed to provide working accommodation for the fourteen Fellows of the Institute. Two groups, one in the mechanics of continua, and the other in probability and statistics, will be carrying out research at the Institute; four survey lectures reviewing particular branches of these fields have been arranged, but the Institute will otherwise remain fairly informal. Further information can be obtained from Dr. J. Gani, Department of Mathematics, University of Western Australia, Nedlands, Western Australia.

Symposium on National Health Institutes

A CELEBRATION will be held on December 12 to commemorate the twenty-fifth anniversary of the founding of the Istituto Superiore di Sanità of Rome. This reunion is being held concomitantly with the first international symposium on "National Health Institutes and Actual Research and Medico-sanitary Problems". The symposium is being sponsored by the World Health Organization, under the auspices of the Italian Minister of Health and the Istituto Superiore di Sanità. The topics to be discussed at this symposium will be: (1) organization of national institutes of health and their function in scientific research and in the safeguarding of public health; (2) national institutes of health and government controls; (3) active intervention of national institutes of health in contingent and specific

problems. Further information can be obtained from the Istituto Superiore di Sanità, Viale Regina Elena 299, Rome.

Announcements

DR. ALBERT WETTSTEIN, head of the Biological Research of CIBA, Ltd., Basle, has been awarded the 1959 prize of the Marcel Benoist Foundation. The prize, which is awarded annually by the Foundation's administrative committee composed of federal government officials, university professors and the French Ambassador to Switzerland, is given to the Swiss scientist who has made the most useful contribution to human life during the preceding year. Dr. Wettstein received this distinction for his outstanding work in the field of steroid hormones.

DR. PAUL E. GAGNON is to succeed Dr. P. Ribeiro de Arruda (Brazil) as director of the International Atomic Energy Agency's Division of Exchange and Training of Scientists and Experts. Dr. Gagnon was governor of Laval University and also dean of the Graduate School at that University from 1940 until he joined the Agency. In 1947 Dr. Gagnon was elected president of the Chemical Institute of Canada.

PROF. M. V. LAURIE, professor of forestry in the University of Oxford, has been appointed a member of the Steering Committee of the Forest Products Research Laboratory (Department of Scientific and Industrial Research) at Princes Risborough in succession to Mr. Harry Douglass, general secretary of the Iron and Steel Confederation. The appointment is for a period of two years.

UNDER its plastics programme, Princeton University is offering a number of fellowships for engineering study and fundamental research in plastics leading to the degree of master of science in engineering. Applicants must hold a first degree in engineering or physical sciences from a recognized institution. The fellowships are valued at 1,500–2,100 dollars, plus tuition and fees. Opportunities for employment as part-time research assistants at 2,100 dollars per annum are also available to students not on fellowships. Further information can be obtained from Prof. Louis F. Rahm, Plastics Laboratory, Princeton University, Princeton, N.J.

THE University of Texas M.D. Anderson Hospital and Tumor Institute is sponsoring a symposium on "The Molecular Basis of Neoplasia" during February 23–25. Further information can be obtained from the Publications Department, University of Texas M.D. Anderson Hospital and Tumor Institute, Texas Medical Center, Houston 25, Texas.

A JOINT meeting of the Challenger Society and representatives of the Marine Laboratories (Development Commissioners' Scheme) will be held at the National Institute for Research in Dairying, Reading, during January 26–27, 1961. Further information can be obtained from Dr. L. R. Fisher, National Institute for Research in Dairying, Shinfield, Reading.

A PUBLIC conference "Education—18 Plus" is being organized by the Communist Party on December 3 at the A.C.T.T. Hall, 2 Soho Square, London, W.1. The conference will discuss the problem of university selection and expansion. Further information can be obtained from the assistant secretary, W. Alexander, Communist Party of Great Britain, 16 King Street, London, W.C.2.

PROGRESS IN AERONOMY

AERONOMY is a new word describing a much older branch of science. It was proposed as recently as 1954 by Prof. Sydney Chapman and refers to the study of the properties of the upper atmosphere and the physical processes occurring in it, particularly those due to solar electromagnetic and corpuscular radiation. That the term is already in general use indicates the rapid growth of interest in this field which has arisen out of the development of new experimental techniques (particularly rockets and satellites) and from the success of the recent International Geophysical Year.

The symposium on aeronomy at Copenhagen during July 19–22 was aimed at surveying recent advances in the subject, both experimental and theoretical, and was organized under the auspices of the International Association of Geomagnetism and Aeronomy. If a digression at this point may be permitted, it may be of interest to direct attention to the close and long-standing link between geomagnetism and aeronomy, arising through the interpretation of magnetic disturbance in terms of electric currents flowing in the outer regions of the Earth's atmosphere. As long ago as 1839, Gauss, in discussing the origin of the terrestrial magnetic field, commented as follows: "If we should look for the direct causes completely or partly in the exterior, we could . . . only think of galvanic currents. The atmospheric air is no conductor of such currents, neither is the vacuum. . . . However, the mysterious phenomena of the aurora in which, to all appearances, electricity in motion acts the main part, forbid us to deny outright the possibility of such currents only because of the uncertainty mentioned and it is, in any case, interesting to study how the magnetic effects of such currents would appear near the Earth's surface". The transition from a possibility not to be denied outright to certainty took a century. Nevertheless, as the proceedings of this symposium amply demonstrate, the mysteries of the aurora and associated phenomena in the upper atmosphere increase in fascination in step with the advances in our knowledge and understanding of them.

The reduction of orbital data of the satellites to yield atmospheric densities at heights up to 700 km. was dealt with by three contributors, D. G. King-Hele (Royal Aircraft Establishment), L. G. Jaccia and C. A. Whitney (Smithsonian Astrophysical Observatory). The method is based on the fact that the satellite loses energy, and decreases in orbital period, through collisions with air molecules; the derived densities represent a mean over about 60° of the orbit near perigee. One of the most interesting features revealed is a diurnal density variation above about 400 km., the day- to night-time ratio being of order 10 at 600 km. height. At these heights there is also a correlation between density and solar activity. S. F. Singer (University of Maryland) discussed, from a theoretical point of view, the distribution of density in the exosphere, that is, in the region where the rate of collision is so low that particles follow ballistic trajectories and some escape entirely from the Earth's gravitational influence. From an analysis of the data on satellite drag, Singer places the base of the exosphere at 530 km. for the neutral constituents. R. A. Helliwell (Stanford University) described how the

properties of the outer ionosphere may be deduced from studies of 'whistlers'. These are low-frequency atmospherics which result when radiation from terrestrial lightning discharges suffers dispersion along propagation paths following the Earth's lines of force. Since the dispersion is greatest at the uppermost point on the path, electron densities out to several Earth's radii can be derived. How the composition of the atmosphere (both neutral and ionized constituents) has been studied by rocket-borne mass spectrometers was the subject of a paper by C. Y. Johnson (U.S. Naval Research Laboratory).

Solar ionizing radiations (ultra-violet and X-rays) were dealt with in papers by R. W. Kreplin (Washington), H. Friedman and R. Tousey (U.S. Naval Research Laboratory). Because of the opacity of the atmosphere in these spectral regions, rocket and satellite-borne instruments are needed to determine the incident flux of the various components. By combining the variation of observed intensity with height in a particular spectral line with laboratory determinations of ultra-violet absorption in atmospheric gases, we can deduce the variation of density with height of the constituent responsible for the absorption. Measurements of soft X-ray intensities indicate their importance as an ionizing agent in the lower levels of the ionosphere. H. Friedman pointed out that since the Lyman α -wave-length coincides with a 'window' in the O I absorption spectrum, this radiation penetrates to about 70 km. altitude and may contribute to the D-region ionization. Rocket measurements of $L\alpha$ made during solar flares have, however, shown no increases within a factor of two.

P. Mange (U.S. Naval Research Laboratory) and V. C. A. Ferraro (University of London) discussed the importance of diffusion in connexion with the distribution of both neutral and ionized constituents of the high atmosphere. Rocket mass-spectrometer measurements of the argon/nitrogen ratio show that these constituents reach diffusive equilibrium somewhat above 100 km., but below this level vertical mixing prevents their separation. The distribution of ionization depends on the rates of ion production and loss, and on diffusion, which is likely to be of greatest importance in the upper F-region. Ferraro presented some theoretical results which take account of the diffusion term and are consistent with the hypothesis that both F1 and F2 regions are produced by the same source of ionization.

A comprehensive review by A. Dalgarno (Queen's University, Belfast) of collision processes relevant to the interpretation of upper-atmospheric phenomena was followed by a number of papers on atmospheric emissions. J. W. Chamberlain (University of Chicago) has derived the total rate of emission from the different components of the airglow and from a bright aurora, using observed spectral intensities. He estimates the total input of energy contributing to a bright aurora to be in the vicinity of 400 ergs cm.⁻² sec.⁻¹. The altitudes of the nocturnal airglow emissions have been the subject of controversy for a number of years, and, in view of their importance in relation to the emission mechanisms, it was particularly gratifying to hear about direct rocket measurements, reported by D. M. Packer (U.S. Naval Research Laboratory). These referred to various radiations

from O, O, OH and Na(D); in all these cases the peak-emitting levels occurred between 80 and 100 km. The variations in the 5577 and 6300 Å. airglow emissions were discussed by F. E. Roach (U.S. National Bureau of Standards) and D. Barbier (Institut d'Astrophysique, Paris). According to the latter author, the 6300 Å. line from O I is the only radiation which is emitted from altitudes greatly in excess of 100 km. Of particular interest was Barbier's recent discovery of stable red arcs emitting the 6300 Å. line at the low latitude of Tamanrasset (in the Sahara). The sodium twilight-glow was the subject of a paper by T. M. Donahue (Observatoire de Meudon, France). At Tamanrasset (21° N.) there is little seasonal variation in abundance of sodium, with about 4.5×10^9 atoms per cm.² (vertical column), whereas at Haute Provence (41° N.) the abundance varies between 2×10^9 and 25×10^9 atoms per cm.².

Spectra of atmospheric emissions contain information about the temperature of the upper atmosphere, but difficulties in both measurement and interpretation are considerable. However, D. M. Hunten (University of Saskatchewan) demonstrated that a temperature profile between 70 and 250 km. can be satisfactorily constructed, using rotational temperatures from N₂⁺ negative bands in aurora and Doppler widths of forbidden lines in the night and twilight airglow.

A general scheme of solar and terrestrial disturbance was presented by T. Obayashi (Hiraio Radio Observatory, Japan). High-energy protons (10–100 MeV.) reach the Earth several hours after solar flares associated with type-IV radio outbursts. These particles cause prolonged polar cap radio-blackouts in the region within geomagnetic latitudes 60–65°. They are followed after a day or so by the corpuscular cloud of low-energy particles travelling at a speed of the order of 1,000 km. sec.⁻¹. The interaction of this conducting cloud with the geomagnetic field produces the main part of geomagnetic storms. Various detailed mechanisms proposed to explain the morphology of geomagnetic disturbance and the nature of the different types of fluctuations were surveyed by

E. H. Vestine (The Rand Corp., Santa Monica, California) in a paper entitled "Problems of Geomagnetism in Relation to Aeronomy". Of great interest in this connexion are the results of rocket and satellite experiments in which many of the features theoretically inferred have actually been measured; for example, the detection of the equatorial current in the E-region by Singer, Maple and Bowen, of the interplanetary fields by *Sputnik III* and the Soviet Moon rocket, and perhaps most exciting of all the discovery of trapped high-energy particles in the Van Allen belts. A particularly interesting finding has been the large magnetic disturbance in interplanetary space at the time of a terrestrial magnetic storm, made by the U.S. *Pioneer V*. Field values of the order of 50γ which were found may be compared with a general background field of 2γ or so.

The influx of interplanetary dust, as determined by various methods, was discussed by me. There remains a gap between the smallest particles producing observable telescopic or radio meteors, and the range of particle sizes detected by rocket and satellite investigations. Satisfactory comparison between the distribution of meteor magnitudes and the distribution in particle momentum or energy as derived from rockets and satellites requires rather more detailed knowledge of the structure of the particles, their orbital distribution, and of the nature of their interaction with the atmosphere than we possess at present.

I wish to conclude by thanking, on behalf of the participants, our Danish hosts, the chairmen of the various sessions, Prof. J. Kaplan (president of the International Association of Geomagnetism and Aeronomy) and Prof. M. Nicolet (chairman of the Association's Committee on the High Atmosphere) for arranging and conducting such a stimulating and rewarding meeting. The papers contributed will shortly appear in the *Annales de Géophysique* and afterwards as a bound volume which, it is hoped, will be available at a price to suit the purse of individual research workers in this rapidly expanding field.

T. R. KAISER

LATTICE DEFECTS AND THE MECHANICAL PROPERTIES OF SOLIDS

THE second symposium of the Fifth Congress of the International Union of Crystallography was held in the Guildhall at Cambridge. It opened with an introductory lecture on August 20 by Prof. N. F. Mott, who surveyed the development of our knowledge about lattice defects and their relation to mechanical properties, and outlined outstanding problems in the field. The symposium, organized by Dr. P. B. Hirsch, occupied August 22–24, and about one hundred papers were presented by contributors from eleven countries. On two days the sessions continued (with a substantial audience) until 10 p.m.; the supposedly free afternoons were, of course, usually fully occupied by private discussions. One may criticize meetings of this kind for the mental indigestion and exhaustion they produce, and argue that fuller discussion on a more restricted subject is to be preferred. Nevertheless, these larger gatherings do have a value of their own in presenting

a broad picture of current progress in many associated fields, and in providing an opportunity for the assembled specialists to assess the impact of related developments on their own particular interests.

The papers of the symposium were grouped under twelve main headings, and it is clearly not possible in the present short review to refer to the significant content of all contributions. Summaries of the papers are printed in the Congress Abstracts of Communications, and the papers will appear in full in the usual scientific journals.

Four sessions were devoted to "Yield Strength" and "Work-hardening", which are perhaps the central problems of the field. Ideas on work-hardening are still in a state of flux, and discussions took place on a number of mechanisms which may be important in determining the flow stress: the stresses due to dislocation groups (Seeger); the debris left behind by moving dislocations (Gilman, who discussed the

velocity of dislocations as a function of stress); also, in a new theory, the associated accumulation of defects by dislocations as they move (Hirsch, Warrington and Hirsch); and the interactions arising from the intersections of dislocations with one another (Baird and Gale, Saada, Hale and McLean). The last authors, and also Howie, and Bailey and Hirsch, reported detailed correlations between observations on thin films and macroscopic treatments and measurements in various metals; and flow-stress measurements were discussed by Christian, Masters, Mitchell and Pargeter, and by Basinski. Other topics treated were the theoretical strength of metals (Richards) and dislocation reactions in body-centred iron (Crussard), while considerable attention was given to the mechanical behaviour of ionic crystals (Newey and Pratt; Pratt; Silverstone and Pratt; Westwood) and of semi-conductors (Bell and Bonfield; Suzuki, Kayano and Watanabe; Bernard, Berth, Burgeat, Devaux, Mme. Soula and Tsoucaris). In the sessions on "Stacking Faults" and "Twinning", two papers were concerned with the direct measurement of stacking fault energies (Howie and Swann) and associated calculations (Bilby, Grinberg and Swinden), and a number of others described the behaviour of faults and twins as observed in thin films and under stress in the electron microscope (Phillips; Price; Fourie, Weinberg and Boswell; Catlin, Walker and Lawless; Pashley and Presland). The last authors also directed attention to fine defects ('black death') produced, probably indirectly, by the electron beam. Two papers discussed the theory of twinning (Christian; Venables) and others treated kinking in cadmium (Blasdale, King and Puttick) and in alkali halide crystals (Mme. Klassen-Neklyudova), and the interplay of twinning and slip in iron (Sleeswyk) and silicon iron (Hull).

In contrast to the situation in work-hardening, the survey of probable mechanisms of "Fracture" could be given (Cottrell) without provoking instant controversy. The influence of minute surface imperfections was emphasized in papers on the Joffe effect (Stokes, Johnston and Li) and on the fracture of glass (Murrell). The former authors also illustrated in another paper the interrelation of fracture and deformation in magnesium oxide. Other papers treated the fracture of zinc (Barnby and Pratt) and silicon iron (Cuff), the fracture of thin metal films (Fujiwara and Yoshida, Fisher and Nutting), and the propagation of cracks (Mme. Shaskolskaya) and the influence of inhomogeneities on this process (Bethge and Schmidt) in alkali halides. The session on "Fatigue" was opened by Thompson, and included reports on thin-film studies of the defects produced (Partridge and Segall), the role of cross-slip (Broom) and a theory of the dependence on temperature (Hirsch and Segall). Grosskreutz described experiments on crack propagation in single crystals.

There were two sessions on "Dislocations and Point Defects"—one on "Quench Hardening" and one on "Climb and Creep". The effects of irradiation and/or cold work and the course of subsequent low-temperature recovery (usually assessed by resistivity measurements) were reported for several materials: in copper and its alloys (Pritchard and Pratt, Sosin), in molybdenum and niobium (Johnson, Peacock and Wronski) and in titanium and zirconium (Smith and Stagg). Effects of straining and ageing on the mechanical and electrical properties and the etching behaviour of alkali halides were also discussed (Slifkin, Kabler

and Layer; Curien and Mihailovic; Bethge and Frohlich; Davidge, Whitworth and Pratt), and an extension of the general theory of strain-ageing reported (Bullough and Newman). Changes in impurity concentration around precipitates at dislocations and other sites in doped silicon were revealed directly by the formation of annular p - n junctions made visible by etching (Newman, Wakefield, Willis and Bullough). Internal friction studies on cold-worked gold and copper (Hasiguti and Okuda) and on quenched aluminium (Gelli and Federighi) were reported, as well as the influence of pressure and plastic deformation on point defects (Lazarus) and their contribution to stored energy and volume changes (Åström). Quench hardening was introduced by Maddin, and a thin-film study of the vacancy clusters produced in aluminium reported by Westmacott, Barnes, Smallman and Hull. The role of solute atoms and vacancies in the ageing of aluminium alloys was studied in thin films (Nicholson), by calorimetric and resistivity measurements (Borelius and Larsson), and by small-angle X-ray scattering (Gerold and Schweizer). An introductory paper on climb and creep (Friedel) was followed by a direct thin-film investigation of the shrinkage-rates of dislocation loops in zinc by climb (Price). An example of the direct and subtle experiments now possible was afforded in a paper by Dash, who was able to argue that climb observed in silicon due to the introduction of gold was due to vacancy deficiency, since left-hand screw dislocations formed right-hand helices. In similar vein, Barnes and Mazey showed that certain dislocation loops in copper foils induced by α -particles were formed by condensed interstitials, since in a foil where the particles come to rest the loops grow during the precipitation of helium bubbles, which is a process requiring vacancies. Other papers in the two sessions on "Radiation Damage" included work on copper and other face-centred cubic metals (Blewitt, Coltman, Jamison and Redman; Silcox; Makin, Whapham and Minter; Seeger, Mader and Eschmann), on graphite (Williamson and Baker; Fujita and Izui) and on fission in uranium steel (Baker and Nutting). A general discussion of dislocation-point defect interaction was given by Sosin.

The session on "Recrystallization" and related phenomena included thin-film investigations on silver (Bailey) and work with other techniques on a titanium molybdenum alloy (Schofield and Bacon) and on aluminium (Weissmann, Imura and Nakayama; Fujiwara and Takano). Grain-boundary motion in sintering was discussed by Horstra and van Bueren. In the session on "Alloy Hardening", A. Kelly reviewed the yield strength of alloys, and thin-film observations on the dislocations in ordered alloys were discussed in two papers (Pashley and Presland; Marcinkowsky, Brown and Fisher). Work was also reported on the order and precipitation hardening in a nickel (24 per cent), chromium (15 per cent), aluminium (3.5 per cent) austenitic steel (Blackburn and Nutting), and of dislocations and precipitates in an austenitic steel containing niobium (Arrowsmith and Nutting).

The final session, on "Martensitic Transformations", was introduced by Read, who also discussed the plasticity of metals undergoing polymorphic transformation. Again, important work using the thin-film technique is revealing here the fine details of the transformation process. P. M. Kelly reported thin-film work on high- and low-carbon steels and on

iron-nickel alloys, and suggested correlations between the twinning and different morphologies observed and the martensite hardness. Venables has worked on thin films of stainless steel transformed by cold work, where stacking faults, regions of hexagonal α -phase and regions of body-centred cubic α' -phase can be seen. Other papers in this session described extensions to the crystallographic theory (Wechsler and Otte) and etch-pit investigations of dislocations in the austenite (Reed and Greeson).

Thus, the subject of defects in crystals continues to expand at an ever-increasing rate, particularly under the stimulus of the development of experimental techniques permitting direct observation of dislocation lines, of which the dominant one is now

the use of the electron microscope to examine thin metal films by transmission. With these high-resolution studies, our knowledge of the detailed behaviour of individual dislocations and other lattice defects is increasing rapidly, and the next ten years will see a great extension in work of this kind. While possible differences in the behaviour of defects in thin films and bulk specimens must always be borne in mind, it is clear that much valuable information about the basic mechanisms controlling bulk mechanical properties will be obtained in this way. Such information must indeed play an essential part in the solution of the more difficult problems concerned with the development of theories about the bulk mechanical properties of practical interest. B. A. BILBY

CO-ORDINATION CHEMISTRY

A SYMPOSIUM on Co-ordination Chemistry with an international attendance was held in Prague during September 5-8. It was organized by the Czechoslovak Chemical Society and by the Faculties of Inorganic Chemistry of the Charles University and the Technical University and sponsored by the Czechoslovak Academy of Sciences.

The introductory paper by Prof. A. A. Grinberg (Leningrad) consisted of a survey of the development of co-ordination chemistry in the past decade and a general review of the present position of the subject. This was followed by a general discussion of the applications of polarography by Dr. A. A. Vlček, a member of the Polarographic Institute at Prague. Dr. Vlček emphasized, in particular, the importance of searching for new complexing agents which would permit the electro-deposition of a wider range of metals than can at present be utilized in this way.

The other scientific meetings were grouped into three sections, concerned with modern preparative methods, with the physico-chemical properties and structure of complexes, and with direct methods of structure determination, respectively. Prof. S. Herzog opened the first main session with a paper on the properties of low-valency co-ordination compounds of metals with dipyriddy and phenanthroline. He described some remarkable substances, for example, zero-valent *trans*-dipyriddy derivatives of titanium, scandium and even niobium. The existence of such compounds and of magnesium and lithium dipyriddy derivatives was shown to raise a number of important problems in valency theory which were discussed in some detail. Whether these compounds are to be regarded as true low-valency compounds of the metals, or as complexes of the dipyriddy anion radical, was the interesting question which emerged in discussion.

Among the contributed papers one can mention only a few. Prof. E. O. Fischer (Munich) described the preparation of a variety of mixed diene-carbonyl complexes of zero-valent metals and discussed some very remarkable rearrangements which they undergo. Prof. I. I. Chernaev (Moscow) described his extensive work on the nitro complexes of tetravalent platinum. Dr. K. Isslieb (Jena) described a large number of novel complexes of transition-metal ions with primary and secondary phosphines. Complexes of tri- and tetra-dentate arsenic ligands were discussed by a group from Oxford.

The section on physico-chemical methods was opened by Dr. L. E. Orgel (Cambridge), who gave an elementary account of the principles of ligand-field theory and of modern methods of determining the spatial distribution of unpaired d electrons in transition-metal complexes. This was followed by an entertaining paper by Dr. L. G. Sillen (Stockholm), who summarized the extensive research of his school on the varied hydrolysis reactions of metal ions in aqueous solution.

Madame B. Jezowska-Trzebiatowska (Warsaw) described the use of optical and magnetic measurements in discussing the electronic structure of a variety of co-ordination complexes. The *trans* effect in a variety of complexes of divalent platinum, trivalent cobalt and divalent copper was treated in a series of papers.

A further group of papers dealt with applications of polarographic methods. Prof. K. B. Yatsimirskii (Kiev) described ingenious methods of using the catalytic polarographic currents to study complexes in solution; Miss D. Wagnerova (Prague) discussed the polarographic reduction of ruthenium nitrosyls, and Dr. E. Fischerova described similar work on trivalent chromium complexes.

The final section was opened by Prof. Porai Koshitz (Moscow), who gave a concise summary of the present state of our knowledge of the environments of metal ions in co-ordination compounds as determined by direct X-ray studies. There followed a series of papers describing structural studies on individual compounds. One may mention in particular papers on the periodate of trivalent copper, on the dipyriddy adduct of the dimer of copper acetate, and on $(\text{NH}_4\text{CH}_2\text{CH}_2\text{NH}_4)\text{CuBr}_2$. Another paper in this series by Czech crystallographers discussed the mechanism of the substitution reactions of cupric compounds.

The meeting as a whole provided an excellent opportunity for the exchange of ideas and information between scientists of all countries. For those from the Western countries it was a particular pleasure to meet and talk with their opposite numbers from Eastern Europe. Apart from the main scientific business of the meeting, foreign delegates were most hospitably entertained—a tour of the medieval city of Prague, an excursion to neighbouring points of interest and the various social activities in the evenings were greatly enjoyed by those present. L. E. ORGEL

ADMISSIONS TO BRITISH UNIVERSITIES

THE second report of an *ad hoc* committee of the Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom on Procedure for Admission of Students (pp. vi+31. London: Association of Universities of the British Commonwealth, 1960. 2s.) deals first with the action taken by the universities on some procedural recommendations of an earlier report published in May 1958 by an *ad hoc* committee. Although the new system has been in operation for only one full year, it is already clear that a marked improvement has occurred. Indeed, 86 per cent of heads of schools answering the independent inquiry of the Joint Committee of the Four Secondary Associations about delays by universities were satisfied that there was no unreasonable delay, and 66 per cent were satisfied with the decisions themselves. Throughout the universities, all those concerned are showing the utmost willingness to co-operate in making the selection and admission of students as simple, fair and rapid a process as possible. As all those concerned, in universities and schools, become more accustomed to the new procedures, the improvement should continue, and to this end the Committee recommends that the normal date for the receipt of applications should continue to be January 31 of the year in which entry is desired (the preceding November 30 for medicine, etc.); constant care should be exercised to preserve standards of precision in letters making offers of places, and the great importance of making as many early decisions as possible is specially emphasized. The Committee also reviews some con-

tinuing problems such as multiple interviews and clearing houses, and recommends that experiments should be tried, worked by volunteer professors in limited fields such as chemistry, physics, biology, medicine, dentistry, veterinary science, agriculture and law. Finally, it recommends that the admission of students generally be kept under review. The Committee of Vice-Chancellors and Principals has already invited this *ad hoc* committee to continue its consideration of future problems.

Figures for applications and admissions for 1959 show that applications to university institutions in England, Wales and Scotland were 117,300, 7,600 and 9,100, respectively, and the corresponding admissions to first-degree courses were 14,960, 1,650 and 3,720, respectively. As between the main categories, applications were distributed as follows: arts, 50,900; pre-science, 40,700; technology, 21,700; medicine, 13,100; dentistry, 4,500. The ratio of applications to the number of places available varies widely between individual universities; for example, from 6.0 to 11.4 in England, 3.8 to 6.2 in Wales, and 1.9 to 3.0 in Scotland, but no clear pattern, according to age or type of institution, emerged from more detailed examination of the figures.

Appended to the report is a brief guide for the sixth-former entitled "Getting into a University", containing the minimum information which any intending candidate needs before discussing matters with those who will give him advice and before completing his application.

INTERNATIONAL UNION FOR CONSERVATION OF NATURE AND NATURAL RESOURCES

RELEVÈQUE was appointed by Unesco to undertake a new mission to the Galapagos Islands. The purpose was to consolidate the basis for the establishment of a research laboratory, the primary objective of the Charles Darwin Foundation. He has now presented a report which contains a wealth of information about the destruction being wrought on the exceptional fauna of the archipelago*.

In his inventory of the present state of the animal populations, Levêque recalls that the sea-lion has succeeded in holding its own in face of the depredations of fishermen, but the fur-bearing seal (*Arctocephalus australis*) is prey to exploitation which will soon lead to extinction if drastic measures are not taken. Biological study of the species must be a priority in the programme of research.

Concerning the bird populations, the maintenance of which is bound up with the survival of the shrub cover of the islands, Levêque is less pessimistic. The larger species call for attention: albatross, flightless cormorant, penguins and especially the flamingo, which is in keen demand for its feathers, and consequently vulnerable.

The author has nothing essential to add to the excellent material on reptiles previously compiled by Mr. Eibl-Eibesfeldt. Wild pig destroy the eggs of the sea iguana, but apart from this the latter species is practically without enemies; the land iguana is holding its own.

By far the most threatened species is the giant tortoise; the local position is desperate. The massacres continue, with the destruction of eggs by feral pigs, by trading shells, and extraction of oil. It appears necessary to destroy the feral pig if the tortoise is to be saved. Levêque calls for the establishment of a large park to be fenced off with barbed wire, and gives suggestion for its boundaries.

Crayfish are being captured on a reckless scale; a single boat recently brought in three tons of crayfish tails in a few days; a thorough study of the biology of the species is required. Likewise, overfishing of the bacaleo will soon result in a serious depletion of this species.

The author lays strong emphasis on the disastrous consequences resulting from the introduction of exotic species to the Islands: dog, donkey, but especially pigs, "the worst enemy of the indigenous

* *Bulletin of the International Union for Conservation of Nature and Natural Resources*, 9, Nos. 1-2 (1960).

agriculture, flora and fauna", and feral goats, which are on the increase and destroy numbers of plants. It would seem advisable to encourage unrestricted hunting of these animals; the fate of the Galapagos Islands, otherwise, will be similar to that of the Mexican island of Guadeloupe. Levêque emphasizes the mistake of prohibiting hunting of feral animals introduced to the Islands. The result is contrary to the objective pursued; the defenceless native fauna, the destruction of which does not require the

use of fire-arms, pays the consequences and serves as food for the settlers.

A number of sound recommendations conclude the survey: engagement of an experienced botanist to undertake methodical inventory of the plant species represented; careful study of the biology of the land tortoise, and, later, of both iguanas, *Amblyrhynchus* and *Conolophus*; efforts in the fields of oceanography and meteorology resulting in a marine research scheme and the establishment of climatological stations.

INDUSTRIAL HEALTH

THE annual report of the Chief Inspector of Factories on Industrial Health in 1959 follows the pattern of the two previous separate reports, and this year includes a special chapter on "Dusts and Their Effects on the Lungs". The establishment at headquarters of the new pathological laboratory permitted a substantial increase in the number and variety of tests, and the combined chemical and pathological work has made possible the examination of an increasing number of workers. The Chief Inspector again emphasizes his anxiety to foster the liaison between the medical branch of the Inspectorate and members of the medical profession generally, which he regards as of great importance if due weight is to be given to significant occupational factors in the health of work people. The 532 cases of industrial poisoning or diseases, notified under the Factories Act, 1937, and the Lead Paint Act, included 64 non-fatal cases of lead poisoning, 6 cases (1 fatal) of anthrax and 25 non-fatal cases of aniline poisoning; 226 notified cases of epitheliomatous ulceration included 9 fatalities, and there were 192 cases of chrome ulceration, while 14 of the 206 gassing accidents were fatal.

The First Aid in Factories Order, 1938, was superseded by the First Aid Boxes in Factories Order,

1959, on January 1, 1960, which brings the contents more into line with modern practice than under the 1938 Order. Interdepartmental discussions on the general principles of first-aid treatment were attended by independent medical experts nominated by the Medical Research Council and members of the Advisory Panel in Ophthalmology were consulted on the first-aid treatment of eye injuries, while at the two meetings during the year of the Industrial Health Advisory Committee the possibility of developing and extending medical supervision in factories was the main subject discussed.

Publication of a new booklet, "Toxic Substances in Factory Atmospheres", was approved. The special chapter on dusts and their effects on the lungs points out that it is now becoming increasingly doubtful whether it is safe to assume that any finely divided dust is harmless if inhaled in sufficient quantity over a sufficient period. Certain dusts, too, may produce an acute inflammatory response in the lungs when they are breathed, and others, usually after many years, may bring about a cancerous development in some part of the respiratory tract. The chapter outlines some general principles on measures required to protect workers against inhaling injurious dusts as well as briefly summarizing existing knowledge about the action of particular classes of dusts.

X-RAY DIFFRACTION STUDIES OF THERMALLY DECOMPOSED PERMANGANATES

By P. J. HERLEY and Dr. E. G. PROUT

Chemistry Department, Rhodes University, Grahamstown, South Africa

THE thermal decomposition of crystals of silver¹, potassium², rubidium³, caesium⁴ and barium⁵ permanganates in high vacuum yield pressure-time plots which are sigmoid in form. The plots for the decomposition of crystals of potassium permanganate (13.6 mgm.) and silver permanganate (20.6 mgm.) at 217° C. and 110° C., respectively, are shown in Figs. 1 and 2. The acceleratory and decay portions of the curves for the above permanganates, except silver permanganate, are described by the Prout-Tompkins equation⁶:

$$\log [p/(p_f - p)] = kt + c$$

where p_f is the final pressure. The plots for the decomposition of silver permanganate obey a modified form of the equation¹, namely:

$$\log [p/(p_f - p)] = k \log t + c$$

These equations follow if it is assumed that at the commencement of the acceleratory period strain exists in the crystal at the interface between the product formed prior to acceleration and the undecomposed material. This strain produces micro cracks in the reactant surface, and the reaction progresses inwards by a mechanism of branching planes of reaction. Mechanical disruption of the crystal, as in the case of potassium permanganate, is a consequence, not the cause, of branching. Silver permanganate, for example, does not disintegrate during reaction. It is of interest, therefore, to examine the Laue photographs of potassium permanganate and silver permanganate at different stages during decomposition when lattice distortion would be expected for both substances. Such distortion will be shown by asterism of the diffraction spots. Fig. 3. A, B, C, D, E, F, G were taken at 40 kV. and 20 m.amp. using

Fig. 1. Pressure-time plots for decomposition of potassium permanganate at 217° C. Curve L, unirradiated crystals; curve M, γ -ray irradiated crystals. Laue photographs taken at times of interruption indicated by arrows. Fig. 3, A, B, C, D and Fig. 4, H, I, J, K correspondingly lettered

copper radiation filtered through iron. The silver permanganate crystal was mounted about the needle axis. The crystal of potassium permanganate was similarly mounted before disintegration, but after this there was no known orientation. The corresponding times of interruption of the reactions are indicated in Figs. 1 and 2.

Asterism is not exceptionally pronounced immediately prior to acceleration, but with both silver and potassium permanganates there is a marked increase in the lattice distortion immediately after this.

Fig. 4, H, I, J, K are Laue photographs of pre-irradiated potassium permanganate (γ -ray dose in spent fuel facility at Harwell, 10 Mrads; $p-t$ plot in Fig. 1) under the same conditions as for Fig. 3. The Laue photograph of undecomposed irradiated material does not differ in any marked respect from that for undecomposed unirradiated potassium permanganate (Fig. 3A). It is seen that the amount

Fig. 2. Pressure-time plot for decomposition of silver permanganate at 110° C. Laue photographs of Fig. 3, E, F, G taken at corresponding times of interruption shown by arrows

of strain is extremely high at the end of the induction period. This is in accord with the suggested mechanism of decomposition of pre-irradiated potassium permanganate⁵, which presumes that at the end of the induction period there are centres of decomposed material throughout the crystal and that these produce a high degree of strain in the solid.

Fig. 3. Laue photographs of unirradiated potassium permanganate and silver permanganate. See legends for Figs. 1 and 2

Fig. 4. Laue photographs of pre-irradiated potassium permanganate. See legend for Fig. 1

More detailed X-ray studies of unirradiated and irradiated permanganates are in progress, and the results will be published elsewhere in due course. We wish to acknowledge financial assistance from the Council for Scientific and Industrial Research (South Africa) and for a scholarship held by one of us (P. J. H.).

A CONNEXION BETWEEN P_c AND THE F REGION

By DR. H. J. DUFFUS

Canadian Services College, Royal Roads, Victoria, British Columbia

THE two most promising theories of the origin of geomagnetic micropulsations of the P_c type are: (1) they originate as standing hydromagnetic waves within the ionosphere¹, or (2) they originate as standing hydromagnetic waves in the outer atmosphere².

Each of these theories has at least one major difficulty to overcome. The first must explain how phase stability can be produced over distances large compared with the thickness of the ionosphere; and why the modulation envelope of P_c wave trains should often be so similar at places as widely separated as College, Alaska, and the Borrego Desert in California. The second must explain how the electromagnetic field appears to be propagated through the lower ionosphere without serious attenuation; indeed, how there can be a maximum of activity on the sunlit side of the Earth where the shielding has been thought to be greatest. This paradox is the main subject of this communication.

White³ has published a curve showing the high harmonic content of the diurnal variation of the ionospheric electron density near the equator. Afanasieva⁴ has reported a similarity between P_c and f_oF_2 (although measured at different places), and a high correlation (0.75–0.97) between P_c amplitude and f_oF_2 . On the other hand, Benioff⁵ reports that his type A oscillations (0.3–2.5 sec. period, and thus not P_c) occur only when the electron density in the F region is unusually low.

These conflicting reports suggested that, averaged over a year, there might be a world-wide relationship between P_c and ionospheric electron density $N(h)$ which is obscured by local effects. A preliminary study of this relationship is now possible since the publication of Miss Hutton's data on the diurnal variation of P_c on the equator⁶, and those of Jacobs and Sinno for the International Geophysical Year⁷; together with the most recent results of $N(h)$ during the International Geophysical Year by workers at the Cavendish Laboratory (Croom, S., Robbins, A., and Thomas, J. O., private communication) and by Schermerling⁸.

As yet there are only enough data to suggest that the diurnal variation of P_c is inversely related to the diurnal variation of the true electron density at 280 km.

Figs. 1a and b respectively show the ratios of the 12-hr. and 8-hr. harmonic components to the 24-hr. component of the diurnal variations of P_c occurrence, and of $N(h)$ at 280 km. over stations covering a large range of geographical latitude. The symbols for the stations are shown along the top of each diagram.

It will be noted that the 8-hr. and 12-hr. ratios are comparable for both P_c and $N(h)$ at all latitudes, although there is considerable dependence on latitude. The harmonic vector lies in the quadrant indicated below each point relative to the 24-hr. vector.

Three different zones are suggested: (1) an equatorial zone, where the corresponding P_c and $N(h)$ vectors are in opposing quadrants; (2) a middle zone, where the effect of the ionosphere is not clearly displayed by this treatment; (3) an auroral or polar zone, where the 8-hr. vectors are in phase, although the 12-hr. vectors oppose one another.

Unfortunately, only the behaviour at the equator is reliably indicated by the present data. The harmonic content in the middle latitudes is so small that slight errors in the data would cause large phase changes, and the high-latitude data are only available from stations in opposite hemispheres.

The simplest interpretation of the equatorial behaviour is that the source of P_c oscillations lies above the ionosphere. At the surface of the Earth the amplitude is reduced by conventional ionospheric

Fig. 1. a, The ratios of the 12-hr. to the 24-hr. harmonic components of the diurnal variation of the occurrence of P_c (dots) and of $N(h)$ at 280 km. (triangles), averaged over the International Geophysical Year, for stations the symbols of which are found at the top of the figure and geographical latitudes at the bottom. The hollow circle is Miss Hutton's (ref. 6) May–July 1957 data. The hollow triangle is Knecht's (ref. 10) f_oF_2 data for the South Pole. b, The ratios of the 8-hr. to the 24-hr. harmonic components of the diurnal variation of the occurrence of P_c and of $N(h)$ at 280 km. at a number of stations. The symbols are the same as in Fig. 1a.

shielding as discussed by Ashour and Pryce⁹. The rather complicated diurnal and latitudinal variations of $N(h)$, together with the too simple assumption of a uniform external disturbance field, have hitherto obscured the ability of their theory to explain the role of the ionosphere in the diurnal variation of P_c .

At high latitudes the 12-hr. phases of both $N(h)$ and P_c are opposed, as they are at the equator. However the 8-hr. components are in phase. Possibly this is due to occasional incursions of solar corpuscles, themselves the source of the hydromagnetic disturbance of the outer atmosphere, which are confined to the auroral zones. It must be noted, however, that not only are the polar data from different hemispheres but also that Knecht¹⁰ observed 3-hr. phase differences between the 12-hr. and 24-hr. components of the F_1 layer and their counterparts in the F_2 layer. Thus considerably more data are required to clarify polar behaviour. Despite the occasions mentioned by Afanasieva⁴ and Campbell¹¹ when the ionization increases during P_c events, a demonstrable effect of the polar ionosphere appears to be that of shielding.

On this basis one may venture to predict that a daily minimum in P_c occurrence will be found corresponding to the daytime maximum in ionization reported by Croom, Robins and Thomas¹², centred on 70° N. during December 1957, and in the southern hemisphere in July. The remarkable absence of P_c during the polar night noted in the International Geophysical Year literature^{4,13} may be associated with this anomaly the origin of which is not understood.

The fact that P_c are found at night at both the equator and at the poles, and can have coherent phases over a thousand kilometres¹⁴, suggests that they can extend simultaneously over the whole surface of the Earth, but with varying amplitude. If this is so, why are they so seldom seen at night in the middle latitudes?

The simplest explanation appears to be that as the average summer month electron density is a maximum at about 20° latitude¹⁵, the P_c field penetrates the local $N(h)$ minimum at the equator. The $N(h)$ diurnal variation is very large at the equator, and it controls the P_c -level. It does not appear to be necessary to postulate a P_c source which is highly dependent on latitude, although Kato and Watanabe's⁸ expression for the outer atmospheric oscillation can have this property.

It is necessary, however, to postulate a source of P_c in the outer atmosphere which is stronger on the sunlit side of the Earth in order to explain the generally low level of night-time P_c . Scholte's study¹⁶ of the propagation of hydromagnetic waves associated with giant pulsations concludes that energy from a rotational transverse disturbance is propagated along the magnetic field without attenuation, and hence is confined to the originating field lines. However, a part of the irrotational disturbance can act to build up a resonance along the magnetic field, and this part falls off inversely as the distance from the source of the disturbance. Thus energy from a localized source travelling with the Sun would be propagated weakly to the dark hemisphere. The amplitude of this 24-hr. component is much greater than the amplitude of the 8-hr. and 12-hr. 'shielding' components in middle latitudes. However, Figs. 1a and b show that they become comparable where the electron density exhibits particularly large diurnal variations, that is, at the equator and at the poles.

The present results do not exclude the possibility that localized hydromagnetic resonance in the upper F region is the source of some P_c disturbances, although the outer atmospheric source seems necessary to explain their large geographical extent. Local oscillations are necessary to explain the phase-changes and differences in wave-form sometimes observed over distances of a few kilometres^{5,13,17}. One would expect them to be excited according to Lehnert's¹ theory.

The equivalent current system for a number of P_c calculated by Jacobs and Sinno⁷ show the disturbance to be concentrated in the auroral zone. Such a picture would be consistent with P_c originating as a hydromagnetic resonance in the auroral F region, and being propagated through the F region to lower latitudes as an increasingly attenuated Alfvén wave. The occurrence of P_c at night on the equator rules out this type of propagation as attenuation would have occurred in the middle-latitude part of the path. Again, we are drawn to the outer atmospheric oscillation as the mechanism producing P_c .

Matsuchita¹⁸ has shown that in general the electron density decreases during the main phase of a magnetic storm, although what happens to the total ionization is not yet clear. A decrease in ionospheric shielding would explain why P_c are generally of larger amplitude during such times, without postulating a change in their source energy. As Matsuchita's effect is dependent on latitude, further study of present data should clarify this point.

If the data of Figs. 1a and b are re-plotted on geomagnetic co-ordinates the similarity between P_c and $N(h)$ disappears. This suggests that the principal attenuation occurs in the lower ionosphere, where there is greater symmetry about the geographical equator. The damping of hydromagnetic waves in the ionosphere depends on the density of the neutral particles as well as on the charged particles. Thus the lower part of the ionosphere should be more effective as a shield than is suggested by its electron density alone. However, the diurnal variation of $N(h)$ is greater in the upper ionosphere. Further study of $N(h)$ data at different heights is required to clarify this very important question of symmetry.

If P_c were produced at the same heights as the S_q currents, one would expect them both to be governed by the ionospheric conductivity, and hence by the symmetry of the geomagnetic field. Thus, on the basis of the present data, I am led to discard the S_q current theory of Terada¹⁹ and to accept a higher source for P_c .

The above arguments show that further documentation of the relationship between the occurrence of P_c and $N(h)$ (better, perhaps, the integrated density over the whole ionospheric column) may rule out one or more of the postulated sources of P_c . In particular, the study of the variations of the upper F region will help decide the question of how local oscillations occur.

The data on which Figs. 1a and b are based are rather scanty. The magnetic data are averaged from October 1957 to September 1958. The $N(h)$ data, although covering the same period, are derived only from ten International Quiet Days in each month, together with Regular World Days of the International Geophysical Year. Furthermore, the $N(h)$ curves pertain only to the 280-km. level because the ionosonde records are most complete for this height. Even so, a number of extrapolated values have been

used, especially in the late evening hours. Only four $N(h)$ stations are complete. The data from the South Pole are only for the month of September 1958⁹. Knecht's¹⁰ values for f_oF_2 are also shown for comparison. They are averaged for the whole year.

There are large seasonal variations in both $N(h)$ and P_e occurrence. Miss Hutton's⁸ P_e data from Legon show that in the summer the 12-hr. component is smaller than the 8-hr. component, although it is larger averaged over the whole year. Similarly the 1939 and 1944 $N(h)$ records from Huancayo show seasonal reversals. The ratios are shown in Table 1. There appear to be even larger changes from year to year, and for this reason care has been taken in this communication to compare data only from the same year.

Table 1. RATIOS OF 12-HR. TO 8-HR. COMPONENTS

$N(h)$	1939	June	1.9	March	0.71
	1944	June	1.6	March	0.60
P_e	1957	May-July	0.72		
	1957	October to			
	1958	December			1.8

I have not distinguished between P_e occurrence and P_e amplitude variation in this discussion, nor considered the effect of the U.T. component of their daily variation. Furthermore, the P_e data include a range of periods which several authors^{4,5,12} would now treat as containing different classes of P_e .

Nevertheless the present data have indicated that P_e are less frequently observed when the electron density at 280 km. is high, providing a P_e source with 24-hr. periodicity is postulated.

This work was done at the Cavendish Laboratory, and the help of J. A. Ratcliffe, Dr. R. Knecht, Dr. J. O. Thomas, Miss A. Robbins and Mrs. S. Croom is gratefully acknowledged. It was supported by a grant from the Defence Research Board of Canada.

REGENERATION OF INSULIN ACTIVITY FROM THE SEPARATED AND INACTIVE A AND B CHAINS

By DR. G. H. DIXON* and DR. A. C. WARDLAW

Connaught Medical Research Laboratories, University of Toronto, Toronto, 4

IT is generally accepted that when insulin is split into its A and B chains by breaking the disulphide bonds, hormone activity is abolished¹. Recent reports²⁻⁴ have indicated, however, that preparations of the isolated chains may possess low levels of activity, but the possibility has not been excluded that traces of intact insulin might be responsible for the effects observed. A variable factor in this work has been in the mode of cleavage of the disulphide bonds. Nicol² used the performic acid method of Sanger (which converts the cystine sulphur into the stable sulphonic acid, cysteic acid) and found low activity in both chains. In contrast, Langdon⁴ employed reductive cleavage followed by conversion of the resulting sulphhydryl groups to phenylmercuric mercaptides. He found that the substituted chains were inactive, but the preparation of B chain developed hormonal activity on removal of the mercury compound with thiol. This suggested that the free sulphhydryl form of the B chain carried the hormonal activity, and it was postulated that insulin might be converted to this form at its site of action.

The present work was started with the object of cleaving the disulphide bonds of insulin by a method which would give the two chains as stable derivatives, readily separable from each other and from unmodified

insulin. These requirements were met by the sulphite method of Swan⁵, which yields the A and B chains as S-sulphonates ($R.SSO_3^-$). These derivatives can be separated readily by ion-exchange chromatography and purified by paper ionophoresis. It was of interest, in the light of Langdon's report⁴, to convert the S-sulpho chains into their free sulphhydryl forms by treatment with excess thiol and to examine the products for insulin activity. Experiments have shown that the chains as the S-sulphonates are inactive, either separately or mixed, which rules out the possibility of the preparations being contaminated with intact insulin. When the S-sulphonates were separately incubated with excess thiol, cysteine or mercaptoethanol, to convert them to the sulphhydryl forms, again no insulin activity was detected. However, incubation of a mixture of the two chains with excess thiol gave rise to definite insulin activity. Since this activity had an ionophoretic mobility similar to that of intact insulin and could be neutralized with a specific anti-insulin serum, it appears that a resynthesis of insulin from the separated chains had taken place.

Preparation of the A and B chains. Ox insulin (1 gm.) was dissolved in 20 ml. of a reagent containing 0.2 M sodium sulphite, 0.08 M cupric sulphate and 8.0 M urea, which had been adjusted to pH 10.2 with ammonia. As judged by ionophoresis, these conditions gave complete splitting within a few

* Present address: Department of Biochemistry, University of Toronto.

Fig. 1. Tracing of an ionophoretogram of S-sulpho A and B chains of insulin. The paper (Whatman No. 3) was wetted with a buffer consisting of 1 ml. of pyridine, 10 ml. acetic acid, 48 gm. urea and water to 100 ml. Ionophoresis was for 60 min. at 75 V./cm. in an apparatus cooled with 'Varsol DX3641' (Imperial Oil, Canada). After drying the paper, the urea was washed out with 95 per cent ethanol. The components were stained by spraying with 1 per cent diazotized sulphanilic acid in 5 per cent sodium carbonate, when the A and B chains appeared as bright orange bands. 1, S-sulpho A chain; 2, S-sulpho B chain purified as described in the text; 3, impure S-sulpho B chain prepared by unmodified procedure of Mycek *et al.* (ref. 6). The minor component in 2 has been shown to be derived from S-sulpho B chain during elution with 1 M ammonia and is likely to be a desamido derivative produced by the alkaline pH.

minutes. The solution was left at room temperature for 2½ hr., then acidified with formic acid to pH 3.2 and the mixture of chains precipitated by adding 10 volumes of 95 per cent ethanol. The chains were fractionated initially by the procedure of Mycek, Clark, Neidle and Waelsch⁶. However, when the preparations were examined by high-voltage ionophoresis on paper, it was found that although the A chain appeared pure, the B chain contained appreciable amounts of A chain (Fig. 1). The contamination of the B chain with A chain was thought to be due to adsorption of A chain on to the B chain which was insoluble in the formic acid solution used by Mycek *et al.* When the procedure was modified to include 8 M urea in the buffer⁷, the B chain stayed in solution. Paper ionophoresis of B chain prepared in this way showed that it was free of A chain (Fig. 1). The modified procedure is as follows: 100 mgm. of the chain mixture was dissolved in 2.0 ml. of buffer solution containing 2.6 M formic acid and 8 M urea and applied to a 2.2 × 9 cm. column of 'Dowex-50X2' (200-400 mesh) in the H⁺ form which had been equilibrated in the same buffer. The A chain, which was not retained by the column, was eluted and then precipitated, together with urea, by adding excess acetone. The urea was redissolved by adding a few drops of ethanol. The A chain flocculated on standing overnight. The B chain was eluted from the resin with 1 M ammonia in 8 M urea and appeared at the alkaline front, leaving the copper behind as a

blue band at the top of the column. Urea was removed from the B chain solution by passage through a 'Sephadex G-50' column equilibrated with 1 M ammonia and the B chain was precipitated by acidification with formic acid.

Treatment of S-sulpho chains with thiols. A and B chain preparations were treated with thiol to remove the sulphonate and regenerate the free sulphydryl group as shown:

The reaction was carried out by making a 50 mgm./ml. solution of the chain preparation in a 0.02 M formate buffer, pH 3.5, containing 8 M urea, and transferring 0.02 ml. (1 mgm.) into a reducing system made up in freshly boiled water. The total volume was 1.0 ml., and the final concentrations were: chain preparation, c. 0.00033 M, *tris*, 0.025 M and an amount of thiol (0.0062 M) which was a 20-fold excess with regard to the molarity of the chain; the final pH was 8.5-9.0. After standing for 30 min. at room temperature the mixture was diluted into a balanced salts solution, 'medium A'*, for biological testing. In biological tests under anaerobic conditions (see below) the medium A was gassed with nitrogen before the reduced chains were added to it.

Biological tests. The preparations were examined for insulin activity by the mouse convulsion test, using the rotating cylinder apparatus of Young and Lewis⁸, and also by a sensitive *in vitro* procedure using mouse hemidiaphragms. The latter test, which is described fully elsewhere⁹, is based on the ability of insulin to stimulate the synthesis of glycogen by muscle tissue incubated in a modified Gey and Gey medium. To test the sulphydryl forms of the chains it was desirable that anaerobic conditions be used, and advantage was therefore taken of the observation that pre-exposure of hemidiaphragms to insulin, at 0° under nitrogen, sensitized the tissues so that they exhibited an insulin effect when afterwards incubated under the usual aerobic conditions of the test. The pre-exposure was done by adding three hemidiaphragms to each reaction tube, which contained 5 ml. of test solution under nitrogen. After 15 min. the tissues were transferred to vessels containing 3 ml. of modified Gey and Gey medium which was gassed with 95 per cent oxygen + 5 per cent carbon dioxide. The tubes were incubated for 90 min. at 37°, when the tissues were taken out and each hemidiaphragm analysed for glycogen by an anthrone method⁹. With each batch of hemidiaphragms, usually 30 per batch, control tests were made to determine the basal level of glycogen synthesis during incubation and also the responsiveness of the tissues to different levels of insulin.

Activities of A and B chain preparations. In early experiments with chain preparations obtained by the unmodified procedure of Mycek *et al.*, it was shown that neither the S-sulpho A nor S-sulpho B chain possessed insulin activity. However, when the S-sulpho B chain was treated with a thiol, cysteine or mercaptoethanol, insulin activity appeared (Table 1). This seemed at first to confirm Langdon's report⁴ that B chain in the sulphydryl form has insulin activity. But ionophoresis of the S-sulpho B chain preparation revealed that it contained appreciable quantities of S-sulpho A chain (Fig. 1), and when this

‡ Prepared by modified procedure described in the text.

was removed by the method described, the S-sulpho B chain no longer showed activity in the presence of thiol (Table 1). Next, the significant observation was made that when S-sulpho A chain was added back to the purified S-sulpho B chain and the mixture treated with thiol, there was a reappearance of insulin activity in a yield of 1–2 per cent. These experiments were all made by the pre-exposure technique using anaerobic conditions although it was found later that the activity was still present when tested under aerobic conditions. These aerobic tests were made by diluting the chain mixture plus thiol into 'medium A' (1.0 ml.), oxygenating and adding 1 ml. 'medium B' to complete the incubation mixture. Mouse hemidiaphragms were added, and, after gassing with 95 per cent oxygen + 5 per cent carbon dioxide, were incubated for 90 min. at 37° prior to glycogen analysis. In this test, as in the pre-incubation test, the yield of insulin activity from the chains was in the region of 1–2 per cent.

The A and B chain preparations were also tested by the mouse convulsion method and showed the same pattern of results, that is, no activity of the separated chains in either the S-sulpho or sulphhydryl forms, but reappearance of activity (1–2 per cent yield) in a mixture of the S-sulpho chains plus thiol (Table 2).

Table 2. ACTIVITY OF THE A AND B CHAINS OF INSULIN COMPARED WITH INTACT INSULIN IN A MOUSE CONVULSION TEST

Preparation	Dose of chain per mouse ($\mu\text{gm.}$)	No. of mice convulsing No. of mice injected

S-sulpho A + thiol	50	0/36
S-sulpho B + thiol	50	2/36
S-sulpho A + B + thiol	50 + 50	55/72
Insulin	1.6	56/72

Nature of the regenerated insulin activity. It seems probable that the regenerated insulin activity is due to the resynthesis of insulin itself from the separated chains. It was thought possible at one stage that the regenerated activity, observed after thiol treatment, might have come not from separated

chains but from insulin molecules in which only one of the inter-chain bridges had been broken by the original sulphite treatment. However, this seems to be excluded by the finding that ionophoretically purified preparations of A and B chain remain inactive when they are treated with thiol separately, but develop activity when they are treated with thiol in a mixture. This finding would also appear to exclude activity being due to complexes such as A-A, B-B, A-mercaptoethanol or B-mercaptoethanol, although it is possible that each of these species is formed during the thiol treatment.

Evidence of a more direct nature that the regenerated activity in the reduction mixtures was due to insulin itself was obtained by ionophoretic and immunological tests. The ionophoresis was done in starch gels prepared with a buffer containing 8 M urea, 0.05 M formic acid and 0.01 M sodium hydroxide at pH 3.7 which was known to give good resolution of insulin (Smithies, O., personal communication). When a portion of the gel corresponding with a marker of bovine insulin was dialysed to remove urea and extracted with acid-alcohol, insulin activity was detected. Adjacent portions of the gel tested in this way were inactive.

The immunological tests were made with an anti-insulin serum prepared by immunizing guinea pigs with ox insulin in Freund's adjuvant, as described by Moloney and Coval¹⁰. The serum neutralized the hormone activity of ox and other mammalian insulins but not that of the codfish. The potency of the serum in a mouse hemidiaphragm test⁸ was such that 1.0 ml. neutralized 600 millunits (24 $\mu\text{gm.}$) of insulin. It will be seen from Fig. 2 that 0.06 ml. serum was required to neutralize the insulin activity present in a mixture of 40 $\mu\text{gm.}$ each of S-sulpho

Fig. 2. Neutralization of reformed insulin activity by specific anti-insulin. The figure shows the relative amounts of glycogen, above the mean basal level, synthesized by individual hemidiaphragms incubated (in groups of three) in mixtures of increasing volumes of anti-insulin with constant aliquots of a solution containing 40 $\mu\text{gm.}$ S-sulpho A, 40 $\mu\text{gm.}$ S-sulpho B and mercaptoethanol. The dotted lines are at $\pm$ 1 S.E.

A + B chains, treated with thiol and oxidized with air. This indicates that from the 80 μ gm. of chain mixture 1.44 μ gm. insulin was produced, which corresponds to a yield of 1.8 per cent. The fact that there is such close correspondence in the estimates of yield by hemidiaphragm tests with and without antiserum indicates that the resynthesized material has an immunological specificity indistinguishable from that of ox insulin. Had the immunological specificity of the molecule been changed, then larger quantities of antiserum would be required for neutralization (as is the case with codfish insulin⁸) and the estimates of yield given by tests with and without antiserum would differ. It is likely, therefore, that the resynthesized activity is due to a small amount of material, identical in its folded structure with insulin, rather than to a large amount of material of altered structure and lower activity.

Since resynthesis of insulin appears to occur in mixtures of separated chains, it is essential that before isolated chain preparations, particularly in the sulphhydryl form, are tested for insulin activity, they be free from cross-contamination with the other chain. Preparations which met this criterion appeared to be without significant activity (<0.1 per cent of the same weight of insulin) at the levels tested (Table 1).

Mechanism of resynthesis. It was shown by starch-gel electrophoresis as described above that the isolated S-sulpho chains, on treatment with excess thiol, lost their negatively charged sulphonate groups and were converted quantitatively into more positively charged species which are interpreted as the sulphhydryl forms (equations 1 and 2). One mechanism of disulphide bond formation would therefore be the recombination of the reduced chains in the presence of oxygen. An alternative mechanism of resynthesis could be the result of a displacement of a sulphonate group on one chain by the sulphhydryl group on another:

No final decision can be reached as to which mechanism of resynthesis is operating here, but in experiments carried out with anaerobic solutions, to minimize oxidation, the yield of insulin activity was the same as when the solutions were deliberately oxidized before testing. It must be realized, however, that even when the test solutions are anaerobic, the freshly dissected diaphragm possesses an undetermined content of oxygen. However, there is no evidence that the diaphragm exerts any specific catalytic influence on the resynthesis.

The yields of insulin obtained are not considered to be unduly low in view of the large number of possible molecular species which could be produced by random reformation of disulphide bonds in a system as complex as a mixture of A and B chains with thiol. Experiments are in progress to determine whether the disulphide bridges tend to reform in certain preferred orientations, as with ribonuclease¹¹, and whether recombination can be influenced so as to increase the yield of insulin. However, even with the present yield, it can be said that if chemically synthesized A and B chains were available in mgm. amounts it should be possible to obtain insulin by the above method and thereby provide the terminal step in the total synthesis of a protein with biological activity.

We wish to thank the Insulin Testing Department for the mouse convulsion tests.

SEMICONDUCTIVITY IN PROTEINS AND HÆMOGLOBIN

Enhanced Semiconductivity in Protein Complexes

DRY proteins show a very high resistivity and energy-gap, typical values being $10^{18} \Omega \text{ cm.}$ (20° C.) and 2.8 eV.^{1,2} Decreases in this resistivity value by a factor 10 have been achieved by H atom bombardment³, following a suggestion to convert the protein into a free radical by chemical means⁴. We have now found that a very large effect may be achieved, following an analogy with the effect of chloranil in forming highly conducting complexes with donors such as dimethyl aniline^{5,6} and phthalocyanine⁷. An aqueous solution of bovine plasma albumin was shaken with *p*-chloranil, the excess *p*-chloranil filtered off, and the solution evaporated to form a bovine plasma albumin-chloranil complex film. Such a film contained a very small amount of chloranil, approximately 0.5 per cent, corresponding to 3 chloranil molecules to 1 molecule of bovine plasma albumin. This plasma-chloranil

film in the dry state had a room temperature resistivity of $3 \times 10^{13} \Omega \text{ cm.}$ and energy gap of 1.06 eV., compared with values for a control dry film of bovine plasma albumin of $8 \times 10^{17} \Omega \text{ cm.}$ (extrapolated) and 2.80 eV. Thus the chloranil has raised the specific conductivity of the protein by a factor 3×10^4 . The bovine plasma albumin-chloranil complex showed a weak but definite electron resonance signal, with a *g*-value of 1.998 and a line-width of 6 gauss. There was no optical absorption or photoconductivity at a wave-length corresponding to the energy-gap of 1.06 eV. Bromanil and iodanyl complexes gave very similar results. Admission of water vapour at a vapour pressure chosen to give approximately a Brunauer-Emmett-Teller monolayer over the (relatively small) available surface of the bovine plasma albumin-chloranil complex gave a twelve-fold increase in resistivity. This is in marked contrast to the effect of water vapour in decreasing the resistivity of pure dry proteins, including bovine plasma albumin.

These results may be explained on lines well known for inorganic semiconductors. The chloranil molecules are taken to accept electrons from the protein, creating positive holes in its conductivity band⁶. On the other hand, water is an electron donor, and by neutralizing positive holes lowers the conductivity of the bovine plasma albumin-chloranil complex. Ammonia gas shows a similar electron-donor behaviour to water, as would be expected. The twelve-fold increase in resistivity is consistent with a filling up of the positive holes (10^2 increase) followed by a donating of electrons into the conductivity band (10^2 decrease). It seems probable, therefore, that in the living cell proteins may show *N* (negative) or *P* (positive) behaviour, depending on their environment, whether aqueous or lipoidal, presence of electron acceptors, free radical sources, etc. It is possible that further work will show that such changes in conductivity may result in steady-state values sufficiently high to be significant for models of electron-transport¹, carcinogenesis² and other phenomena in the living cell.

Semiconductivity in Hydrated Haemoglobin

HEMOGLOBIN is regarded as a model for a large class of oxidation enzymes, where electron mobility may be of biological significance¹⁰. In the dry state its very low specific conductivity, about $10^{-18} \Omega^{-1} \text{ cm}^{-1}$ at 30° C , is attributed to electron and hole mobility¹ in the $\text{CO} \dots \text{HN}$ bridge system⁸. Water is adsorbed on natural, or methanol-denatured, haemoglobin, corresponding to a Brunauer-Emmett-Teller 'BET monolayer volume' V_m of $319 \text{ moles}/10^6 \text{ gm. protein}$, whereas a close-packed monolayer of water molecules over all the molecular surfaces throughout the crystal would involve $1,160 \text{ moles}/10^6 \text{ gm. protein}$ ¹¹. The molecular dimensions for the latter calculation are taken from X-ray data¹² which also show that water molecules do not penetrate within the actual molecules, but only over the molecular surfaces. We have studied the effect of adsorbed water on the semiconductivity of a solid specimen of methanol-denatured haemoglobin, allowing three days for equilibrium for each point. The result in Fig. 1 shows that there is a large increase in conductivity which reaches a constant value at about V_m . Thereafter, there is little change until a relative vapour pressure of about 0.9, corresponding to $4V_m$, when the conductivity increases sharply to about $10^{-8} \Omega^{-1} \text{ cm}^{-1}$ at 30° C .

Following the result of the previous communication it, is suggested that initially water molecules are held on special sites and donate electrons into the conductivity band of the protein molecule giving an 'N-type (negative) protein', where a high mobility is expected throughout the crystal⁸. To accord with earlier suggestions¹³, and the increase in conductivity, these sites may be CONH groups adjacent to polar side chains. This view differs from that of Baxter¹⁴, who suggested that electrons tunnelled from one adsorbed water molecule to the next. As the physical surface becomes filled up around $4V_m$, we expect proton conduction to set in within the monolayer of adsorbed water, along lines suggested by Rich¹⁵. Proton conduction, with $10^{-8} \Omega^{-1} \text{ cm}^{-1}$, has been

Fig. 1. Specific conductivity σ , $\Omega^{-1} \text{ cm}^{-1}$ as a function of adsorbed water for nylon at 25° C . (N) (ref. 9), keratin at 25° C . (K) (ref. 9), gelatin at 32° C . (G) (ref. 11) and haemoglobin (H) at 30° C . The arrows mark the values of the Brunauer-Emmett-Teller monolayer adsorption (refs. 11 and 17)

demonstrated for keratin with 15 per cent water¹⁶, about $2.5V_m$ ¹⁷ (see Fig. 1). Similar 'high' specific conductivities may be calculated for gelatine with $2.5V_m$ adsorbed water¹⁸. It may be that the relatively marked effect of water on the conductivity of these two fibrous proteins, and its even more marked effect on nylon^{16,19} point to the operation of yet a third effect due to adsorbed water on flexible chain molecules containing CONH groups, that is, the plasticizing effect of water molecules on chain movement, facilitating transfer of protons between NH and CO groups in different chains, first described by Baker and Yager¹⁹.

EVIDENCE FOR THE INVOLVEMENT OF A TRYPTOPHAN RESIDUE IN THE REACTION OF DIISOPROPYLPHOSPHOROFUORIDATE WITH α -CHYMOTRYPSIN

By JOHN F. WOOTON and PROF. GEORGE P. HESS

Department of Biochemistry, Cornell University

THE inhibition of chymotrypsin by diisopropylphosphorofluoridate was first reported by Jansen, Nutting, Jang and Balls¹. In this stoichiometric reaction^{2,3} an aliphatic hydroxyl group of a serine residue in the active centre of chymotrypsin is implicated⁴. Evidence is presented in this communication which indicates that a tryptophan residue is also involved in the reaction of diisopropylphosphorofluoridate with α -chymotrypsin.

The difference spectrum of diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin (three times crystallized α -chymotrypsin, Worthington Biochemicals, Freehold, New Jersey) at pH 6.7 is illustrated in Fig. 1a. Identical solutions of α -chymotrypsin are added to the sample cell and to the reference cell of a Cary model 14 self-recording spectrophotometer. Approximately three times the stoichiometric amount of diisopropylphosphorofluoridate in dilute isopropanol is added directly to the sample cell while an equivalent aliquot of dilute isopropanol is added to the reference cell. The solutions are scanned 3 min. after addition of diisopropylphosphorofluoridate and at intervals up to 30 min. later. No spectral changes are observed on standing, indicating that the reaction is complete in 3 min. at this pH, and that the spectral change is due to the addition of diisopropylphosphorofluoridate and not to any progressive change of the control solution due to autolysis.

Nitrogen⁵ and phosphorus⁶ determinations on exhaustively dialysed samples of diisopropylphosphoryl α -chymotrypsin prepared using 3 and 10 times the stoichiometric amount of diisopropylphosphorofluoridate showed a phosphorus content of 1.16 moles per mole of enzyme, based on a molecular weight of 25,000 and a nitrogen content of 16.5 per cent. This is in good agreement with the previously reported value¹.

The difference spectrum of diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin appears to be due to the specific reaction of an acylating agent with the active site of the enzyme. When α -chymotrypsin denatured by 8 M urea or α -chymotrypsinogen are treated with a ten-fold excess of diisopropylphosphorofluoridate, and these samples are scanned versus their respective control sample, difference spectra are not observed. The difference spectrum of diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin is essentially the same as the difference spectrum of one of the monoacetyl- α -chymotrypsins⁷ versus α -chymotrypsin (Fig. 1b). Above pH 6.0, where monoacetyl- α -chymotrypsin deacylates, the difference spectrum disappears with time. The rate of change of ΔD 290 appears to follow the known rate of deacylation of monoacetyl- α -chymotrypsin at the same pH and temperature.

A series of experiments were carried out in order to differentiate between various types of interactions which could result in the appearance of the difference spectrum of diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin. (1) The relationship between ΔD 290 and concentration of diisopropylphosphoryl- α -chymotrypsin follows Beer's law up to a concentration of 1.15 mgm. of diisopropylphosphoryl- α -chymotrypsin per ml. (Enzyme concentrations were determined spectrophotometrically at 280 m μ using $E(280, 1 \text{ per cent}) = 20.0$ to relate extinction to enzyme concentration⁸.) (2) The difference spectrum is stable over the pH range 1-11, both in water and in 8 M urea. Large changes in ionic strength do not

Fig. 1. Ultra-violet difference spectra. a, Diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin, enzyme concentration $\approx 3.6 \times 10^{-4}$ M, pH 6.7, 0.033 M *tris* hydrochloric acid, 0.033 M calcium chloride, 1.1×10^{-4} M diisopropylphosphorofluoridate, 25° C.; b, monoacetyl- α -chymotrypsin versus deacylated control, enzyme concentration $\approx 2.4 \times 10^{-4}$ M, pH 6.7, 0.033 M *tris* hydrochloric acid, 0.033 M calcium chloride, 25° C. Spectrum obtained 6 sec. after adjusting pH of monoacetyl- α -chymotrypsin solution to 6.7; c, effect of ionic strength on difference spectrum of diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin, enzyme concentration $\approx 3.6 \times 10^{-4}$ M, 25° C. The enzyme samples were dialysed at 4° C. for 72 hr. against several changes of de-ionized water. The ionic strength was adjusted by addition of sodium chloride. —, $\mu = 0.5$ M; ---, $\mu = 6 \times 10^{-4}$ M; d, diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin in 8 M urea, enzyme concentration $\approx 3.6 \times 10^{-4}$ M, pH 7.0, $\mu = 0.2$ M, 25° C.

appreciably affect either the magnitude or the position of the principal peak of the difference spectrum at 290 m μ (Fig. 1c). (3) The difference spectrum of diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin persists after denaturation of the enzymes in 8 M urea at pH 7.0 for 48 hr. at 37° (Fig. 1d). It has been demonstrated⁹, using optical rotation as criterion, that both chymotrypsin and chymotrypsinogen are completely denatured in 7 M urea at 0° C. after 2½ hr. Diisopropylphosphoryl- α -chymotrypsin is more rapidly denatured in urea than chymotrypsinogen¹⁰.

The data presented so far suggest that the spectral shift responsible for the 290-m μ peak is not due to some form of intermolecular interaction, intramolecular hydrogen bonding, a simple dipole-dipole interaction, a change in dielectric constant of the medium surrounding the chromophore, or a charge effect.

The findings are consistent with a strong interaction involving either a tyrosine or a tryptophan residue in diisopropylphosphoryl- α -chymotrypsin, since both these residues absorb strongly in the 280–300 m μ region. In order to differentiate between these two amino-acid residues, advantage is taken of differences in their spectral behaviour at high pH. The characteristic 282 m μ absorption peak of tryptophyl residues in proteins undergoes only slight shifts with changes in pH (ref. 11). The absorption maximum of unionized tyrosyl residues in proteins is approximately at 278 m μ , of ionized tyrosyl residues at 295 m μ . The observable increase in optical density at approximately 295 m μ with ionization of tyrosyl groups makes possible a spectrophotometric titration of these groups¹². Thus abnormalities in the behaviour of tyrosyl groups in proteins due to interaction with other groups are detectable. To determine whether a tyrosyl group ionizes differently at any pH in diisopropylphosphoryl- α -chymotrypsin than in α -chymotrypsin, pairs of samples are compared in both aqueous buffer and in 8 M urea at pH's between 7 and 13.

Table 1. ΔD 295, DIISOPROPYLPHOSPHORYL- α -CHYMOTRYPSIN VERSUS α -CHYMOTRYPSIN

Enzyme concentration, 3.6×10^{-4} M, $\mu = 0.2$ M, 23°. A Beckman model G pH meter was used for pH determinations

8 M urea		Aqueous	
pH	ΔD 295	pH	ΔD 295
7.4	+ 0.002	7.2	+ 0.001
7.8	+ 0.000	7.9	+ 0.000
9.8	+ 0.010	9.3	+ 0.000
9.8	+ 0.006	9.8	+ 0.013
12.3	+ 0.004	11.8	+ 0.005
13	+ 0.002	12.6	+ 0.003

As can be seen from Table 1, there is no significant difference between diisopropylphosphoryl- α -chymotrypsin and α -chymotrypsin in the ionization behaviour of tyrosine residues. The data suggest that a tryptophan and not a tyrosine residue is modified in diisopropylphosphoryl- α -chymotrypsin.

This suggestion is supported by studies of the reaction of N-bromosuccinimide with diisopropylphosphoryl- α -chymotrypsin and α -chymotrypsin. According to previous reports the reaction conditions used in these experiments lead to the selective oxidation of the tryptophan residues to the corresponding oxindole¹³. The reaction was carried out in 8 M urea after the enzymes were allowed to stand in 9 M urea for 24 hr. Under these conditions all tryptophan residues should be equally reactive. It was found, however, that oxidation of tryptophans

Fig. 2. Ultra-violet difference spectra in 8 M urea following reaction of enzyme preparation with N-bromosuccinimide. Enzyme concentrations 3.6×10^{-4} M, pH 4.0, 0.07 M sodium acetate buffer, 25° C. The sample cell contains an enzyme preparation in which 4.0 moles of tryptophan residues were oxidized by N-bromosuccinimide per mole of enzyme; the reference cell contains an enzyme preparation in which 4.5 moles of tryptophan residues were oxidized per mole of enzyme. Curve a, diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin; curve b, α -chymotrypsin versus α -chymotrypsin.

by N-bromosuccinimide occurs less readily in diisopropylphosphoryl- α -chymotrypsin than in α -chymotrypsin. Addition of the same amount of N-bromosuccinimide to identical solutions of α -chymotrypsin and diisopropylphosphoryl- α -chymotrypsin leads to the oxidation of 4.5 ± 0.1 residues in α -chymotrypsin and only 4.0 ± 0.1 residues in diisopropylphosphoryl- α -chymotrypsin. The difference spectra of N-bromosuccinimide-treated diisopropylphosphoryl- α -chymotrypsin versus N-bromosuccinimide-treated α -chymotrypsin, and N-bromosuccinimide-treated α -chymotrypsin versus N-bromosuccinimide-treated α -chymotrypsin are illustrated in Fig. 2. The sample cell contains diisopropylphosphoryl- α -chymotrypsin or α -chymotrypsin in which 4.0 moles of tryptophan are oxidized per mole of enzyme; the reference cell contains α -chymotrypsin in which 4.5 moles of tryptophan are oxidized per mole of enzyme. In both cases the difference spectra correspond closely in shape to an absolute spectrum of tryptophan, but they differ both in position and in the relative intensities of the absorption peaks. The data indicate that the reaction of N-bromosuccinimide with diisopropylphosphoryl- α -chymotrypsin leads to the accumulation of a reaction product which is not found in the reaction of N-bromosuccinimide with α -chymotrypsin.

The results presented suggest that the 290 m μ absorption peak observed in the difference spectra of monoacetyl- α -chymotrypsin versus α -chymotrypsin, and diisopropylphosphoryl- α -chymotrypsin versus α -chymotrypsin, is intimately associated with the specific acylation of the active site of α -chymotrypsin. Since these difference spectra seem identical, it appears that their origin is probably not due to a direct interaction with these substituents, but due to a reversible rearrangement of the active site of the enzyme. The results support the view that this rearrangement involves a strong interaction, resembling a covalent bond, with a tryptophan residue in the enzyme.

These investigations were aided in part by the Office of Naval Research, Department of the Navy

(NR 108-417) and by the National Science Foundation.

DETECTION IN INVERTEBRATES OF INDUCIBLE, REACTIVE MATERIALS RESEMBLING ANTIBODY

By JOHN H. PHILLIPS and BENJAMIN J. YARDLEY

Department of Bacteriology, University of California, Berkeley, California

THOSE reactive substances that are produced by vertebrates in response to foreign materials, and to which the term 'antibody' is generally applied, constitute a collection of proteins of somewhat varied properties. The outstanding common characteristic of these proteins is their reaction with the inducing antigen, although the occurrence of this reaction may be manifested in a number of different ways. Apart from assay methods which involve biological response, for example, toxin neutralization, sensitization, etc., quantitative detection is generally dependent on either the production of a change in state of one or both of the reactants, such as precipitation and agglutination, or the consumption of a third measurable component by the antigen antibody reaction as in complement fixation.

The choice of a method of detection for studies on invertebrates might therefore be made from any of the above procedures. However, there are certain difficulties inherent in each of these approaches. Deviations in behaviour sufficient to be scored as biological responses are not readily judged in such animals as sea anemones. Precipitation and agglutination may be dependent on rather unpredictable conditions in the reaction mixture, for example, the concentration of electrolyte or protein. There is variation in the ability of antibodies from various animals to fix complements of heterologous species.

The methods described here were developed in an attempt to circumvent some of these difficulties. These procedures allow the rapid detection of antibody formation in a variety of invertebrates. In essence, we aim at the detection of any combination between induced substances in the invertebrate and the inducing agent. Such combination is detected through the use of a standardized rabbit antiserum prepared against the inducing antigen. Measured amounts of rabbit antiserum and antigen are added to invertebrate preparations. Any deviation from the expected amount of precipitate due to the combination of rabbit antibody and antigen is taken as presumptive evidence of a combining substance present in the extract of the invertebrate. Further evidence is obtained by demonstrating a relationship between the injection of antigen into the animal and the subsequent increase in activity of extracts. Finally, a

certain degree of specificity must be demonstrated by showing a difference in the effect of the invertebrate extracts on a precipitating system in which a different antigen and rabbit antibody are used.

Investigations on the anemone, *Anthopleura elegantissima*, are reported here. Individual animals were given an injection of 1 mgm. of Armour bovine serum albumin fraction V, contained in 0.1 ml. of artificial sea water¹. In each case an attempt was made to introduce the antigen into the mesogloea, but success or failure was difficult to judge. Most of the animals were placed in a 30-gallon aquarium in which sea water was maintained at 13° C. At the same time, six anemones were placed in small, individual jars containing 50 ml. of artificial sea water and maintained at the same temperature. Since coelenterates are nonvascular animals, extracts were prepared from the whole animals as follows: 5 anemones were removed from the aquarium at desired intervals of time and individually macerated in a Waring blender with artificial sea water containing 1/10,000 merthiolate. The volume of sea water employed was 100 ml., including the volume of the anemone. The water from the six small jars containing individual anemones was collected after the same time intervals and replaced by fresh artificial sea water. The extracts and sea water samples were centrifuged at 15,000 r.p.m. in a high-speed 'Serval' for half an hour at 5° C., and the supernatant filtered through Whatman No. 1 filter paper. The filtrate was then tested for antibody activity.

Two methods of testing for activity have been employed. The scheme of the first is shown in Table 1. Each of the mixtures was set up in duplicate. Incubation was at 5° C. for 24 hr. The mixtures were then centrifuged at 5° C. for 15 min. at 2,000 r.p.m., and the precipitates washed twice with artificial sea water at 5° C. The precipitates were dissolved in 0.1 N sodium hydroxide and the amount of protein measured by the Lowry method², using a calibration curve prepared using bovine serum albumin. The method gave a reproducibility of ± 0.008 mgm. protein.

The second test method involved a similar scheme with the use of 2.0 ml. of test material and one-half the amounts of bovine serum albumin and rabbit

Table 1

Mixture	Test material*	Bovine serum albumin	Rabbit anti-bovine serum albumin diluted 1/5	Rabbit normal serum diluted 1/5	Artificial sea water
1	ml.	0.5 ml. (0.0155 mgm.)	ml. 0.5	ml.	ml. 4.0

* Sea anemone extract or ambient sea water from injected anemones.

anti-bovine serum albumin in a total volume of 3.0 ml. The reactants were placed in 10 mm. cuvettes in the Beckman *D.U.* spectrophotometer, and the turbidity was measured at intervals for 65 min. at a wave-length of 340 m μ using a slit-width of 0.218 mm. and a blank containing rabbit antiserum and artificial sea water. Temperature was maintained at 25° C. The method of measurement is essentially the same as that employed by Najjar *et al.*³. The optical density is observed to increase sharply during the first 30 min. of observation. By 60 min. the optical density becomes quite constant and there is only a small increase in the following 30 min.

Extracts which tended to darken on standing could be cleared by treatment with 'Nuchar C-190-N' activated charcoal (Industrial Chemical Sales Division, West Virginia Pulp Paper Co.). The treatment with 'Nuchar' could not be used prior to the determination of residual bovine serum albumin as this protein is adsorbed during the removal of the interfering brown pigment. No detectable change in the antibody-like activity was produced by the use of the small amounts of 'Nuchar' employed.

In both test methods, the results were evaluated by comparison with a standard curve prepared using rabbit antiserum and bovine serum albumin diluted with artificial sea water. The relationship between the two methods of measurement is shown in Fig. 1.

The levels of bovine serum albumin and anti-bovine serum albumin used in all tests lie in the region of great excess of antibody. The reproducibility of the turbidimetric method was found to be within 0.004 optical density. It was observed that the values obtained by either method of measurement could be evaluated in terms of the other. The use of both methods of assay allows observation of the course of the reaction and a check of the final result.

Mixtures 1-4 acted as controls of the rabbit precipitating-system and were included in each group of tests. No significant difference in the blank values, mixtures 5 and 6, was observed in any experiment. These two mixtures acted as controls of the anemone extract. There was no indication of precipitation in mixture 7, demonstrating a lack of anemone antibody capable of precipitation under the conditions of the tests.

The precipitate in mixture 8 represented residual bovine serum albumin from the injection. The disappearance of injected bovine serum albumin from the animal, as indicated by the tests of the extracts,

Mgm. bovine serum albumin added to 0.5 ml. of rabbit anti-bovine serum albumin diluted 1/5

Fig. 1

follows the course indicated in Fig. 2, which includes a plot of the average amount of residual bovine serum albumin per 4 ml. of extract. From day 12 onwards, the amount of bovine serum albumin remaining was below the level of detection in all anemones. (The level of detection was 2 μ gm. bovine serum albumin.) In no case was bovine serum albumin detected in the sea water surrounding injected anemones. If leakage of this antigen from the animals were responsible for the observed decrease, the albumin released would have been detected, because it would have been contained in half the volume used for preparation of the extracts. It may there-

Fig. 2

* Normal anemones not injected with bovine serum albumin.
 † Anemones immediately after injection of bovine serum albumin.
 ‡ All negative deviations have been corrected to deviation per 5 mgm. of extract protein.

Fig. 3

fore be concluded that the disappearance of the bulk of the injected antigen represents breakdown within the anemone rather than excretion. Examination of extracts over a period of time indicated that there was no destruction of bovine serum albumin due to proteolytic enzymes once the extract was prepared. Since observations on intracellular digestion in oelenterates indicate a distinctly acid condition in vacuoles containing materials undergoing hydrolysis, the observed absence of breakdown may be due to the somewhat alkaline reaction of the extracts due to the use of sea water as extractant⁴.

Fig. 3 shows the deviations from the amount of precipitate expected in mixture 9 observed with extracts prepared from anemones. The expected amount of precipitate varied between 0.11 and 0.13 mgm. of protein, depending on the lot of rabbit antibody and bovine serum albumin used.

All deviations have been corrected for residual bovine serum albumin due to the injection. Since the anemones varied in volume from 2 to 20 ml., the negative deviations have been adjusted to give values per 5 mgm. of extract protein. The positive deviations could not be adjusted in a similar manner for reasons that will be discussed below. The maximum deviations actually measured were +0.05 and -0.128 mgm. protein.

Twenty-four hr. after the injection of bovine serum albumin, extracts appeared to add protein to the rabbit antibody-antigen precipitate. This additive effect gradually disappeared and was replaced by an inhibitory one. At about the eighteenth day after injection, strongly inhibitory extracts were found. Most of the extracts prepared from anemones throughout the remainder of the period of observation showed negative deviations. In an attempt to find a quantitative relationship between the kind of deviation produced and the concentration of anemone material, various dilutions of a strongly inhibitory extract were tested using a constant amount of bovine serum albumin and rabbit antibody. There was a decrease in the negative deviation by 0.0055 mgm. protein for each two-fold decrease in concentration of the anemone material, until the extract had been diluted to the point where

the addition of protein could be observed. The additive effect disappeared on further dilution. Therefore, it appears that the inhibitory substance in anemone extracts is the same substance that is responsible for the positive deviations observed in anemones harvested soon after the injection of bovine serum albumin. The observed relationship between concentration of extract and magnitude of deviation was used in adjusting the negative deviations shown in Fig. 3.

The course of antibody synthesis as indicated by the examination of groups of anemones at intervals of time after the immunizing dose could be duplicated by testing one anemone repeatedly. Before injection, a small piece of tissue was cut from an anemone using a 5 mm. cork borer, and the antibody was extracted in the following manner. The tissue was ground in a chilled 12-ml. conical glass centrifuge tube using an etched glass stirring rod. Lipid and pigments were extracted, using a mixture of 3 parts of 95 per cent ethanol and 1 part of distilled water, previously chilled to -5° C. Two 12-ml. volumes of the ethanol solution were employed and the sediment collected by centrifugation at 2,000 r.p.m. for 5 min. after each extraction. The sediment was washed twice with chilled distilled water, allowed to drain thoroughly and finally extracted with 6 ml. of artificial sea water containing merthiolate. No activity could be observed when the extract from a non-immunized anemone was tested using the bovine serum albumin precipitating system. Bovine serum albumin was injected as described above. At daily intervals, pieces of tissue were removed and extracted. The consecutive extracts revealed again the additive and inhibitory effects described above; inhibitory extracts also showed the additive behaviour on dilution.

The specificity of the anemone material has been examined by the use of a precipitating system consisting of human serum albumin and rabbit anti-human serum albumin. Extracts from anemones immunized with bovine serum albumin did not affect the human serum albumin precipitating system. Extracts from anemones similarly immunized with human serum albumin produce no deviation of the bovine serum albumin precipitating system, but show additive and inhibitory effects when tested with the human serum albumin system.

In summary, there are indications that an inducible reactive substance may be elicited in anemones. This substance appears to have a degree of specificity comparable to rabbit antibody. The additive property of anemone antibody shows some interesting characteristics which are now being investigated.

LETTERS TO THE EDITORS

RADIOPHYSICS

New Limits to the Diameters of Some Radio Sources

THE investigations at Jodrell Bank of the angular diameters of extra-terrestrial radio sources have now reached the stage where interferometric observations are being made with a base-line of 32,000 wave-lengths. The interferometer operates at a wave-length of 1.89 m., and uses the 250-ft. steerable paraboloid in conjunction with auxiliary aerials which are now placed about 40 miles to the west of Jodrell Bank near the Welsh coast. This is the longest base-line to be used so far for the observation of radio sources, and it is possible with this instrument to set new limits to the diameter of some radio sources which are significantly smaller than those previously reported¹.

A preliminary experiment is being carried out to investigate the fringe visibility of those sources which produced a measurable fringe when observed at the last base-line used, which was 9,700 wave-lengths. So far, 91 sources have been studied, and of these 38 have produced a measurable fringe. These sources lie in the area between right ascensions 16 hr. and 6 hr., and between declinations 58° and -21°; they have flux densities in the range $8.5-85 \times 10^{-26}$ W.m.⁻² (c./s.)⁻¹. Each source has been observed at least twice and Fig. 1 is a facsimile of one of the records of the transit of source 3C 147 (R.A. 05h. 38m., Dec. 49° 51', flux density 63×10^{-26} W.m.⁻² (c./s.)⁻¹).

As this is the longest base-line so far used there is no standard radio source of known diameter which can be used to calibrate the observations. The calibration must therefore rely on absolute measurements of fringe amplitude or comparisons with previous observations of the signal to noise ratio of the intense sources. Fig. 2 is a histogram of the results for the 38 sources which produced a measurable fringe. The abscissa is the ratio of the observed fringe amplitude on the recorder chart, corrected only for the polar diagram of the auxiliary aerial, to the flux density listed in the 3C catalogue². This is an arbitrary scale dependent on the gain setting and sensitivity of the interferometer, but it is proportional to fringe visibility. A scale of absolute fringe visibility has been estimated from a comparison of the signal to noise ratio observed for three intense

sources (3C 48, 147 and 459) with that observed at shorter base-lines, and this has been used to set limits to the diameters of the sources. The lower scale on Fig. 2 shows the estimated upper limits to the source diameters. It has been assumed that the sources are simple circular disks with a gaussian distribution of surface brightness; the scale shows the diameters between the points of half-brightness.

These observations will, of course, be affected by confusion and noise. However, the effective solid angle in which confusing sources can be observed is limited by various factors to less than half a square degree. It is estimated that, with this very small area, the error in fringe amplitude due to confusing sources (even if the confusing sources are unresolved) should not exceed 2×10^{-26} W.m.⁻² (c./s.)⁻¹ in 90 per cent of these observations.

These preliminary observations show that out of 91 sources at least seven have major features smaller than 3 seconds of arc, and that these sources have an extremely high surface brightness which is comparable with that of the intense radio source in Cygnus, I.A.U. 19N44. The source I.A.U. 14N54 has recently been identified³ with an object having a recessional velocity approaching half the speed of light. The

Fig. 1. Record of the transit of the source at R.A. 05h. 38m. obtained on September 19, 1960

Fig. 2. Histogram of the normalized fringe amplitudes for the 38 sources which produced measurable fringes at 32,000 wave-lengths resolution. The scale of diameters has been estimated from a comparison of signal to noise ratio at this and shorter base-lines

diameter of this radio source has been estimated, from observations at 9,700 and 32,000 wave-lengths, as $4\frac{1}{2}$ sec. of arc in position angle 090° . This identification supports the view that these sources of small angular diameter and high surface temperature comparable to that of Cygnus A are objects at such great distances that cosmological effects should be significant.

It has been pointed out by Hoyle⁴ and by Davidson⁵ that there is a theoretical lower limit to the observable diameter of a radio source which is dependent on the particular cosmology considered. They have shown that, for sources similar to Cygnus A, this lower limit is 4 sec. of arc for a steady-state universe and 15 sec. of arc for an Einstein-de Sitter universe. The results in Fig. 2 show that a significant fraction of radio sources have an angular size less than the values predicted for either a steady state or an Einstein-de Sitter universe, but in making this comparison it must be remembered that the source Cygnus A is asymmetrical^{6,7} with a ratio of major to minor axes greater than 4. All the measurements reported here refer to position angle 090° , and do not take account of any asymmetry in the sources.

We wish to thank Prof. A. C. B. Lovell for making available the facilities of Jodrell Bank, and both him and Prof. R. Hanbury Brown for their continued interest and advice during the course of this work. One of us (B.R.) is indebted to the Leverhulme Trust for a research fellowship.

Propagation of Whistlers to Polar Latitudes

WITHIN the past three years, whistlers have been heard consistently at a number of stations located on the polar side of the auroral zones. Certain characteristics of polar whistlers have been reported by Martin¹ for Scott Base (geomagnetic latitude 79.3° S.), by Ungstrup² for Godhavn (79.8° N.) and by Helliwell *et al.*³ for Byrd Station (70.6° S.). In each case similarities to whistlers received at lower latitudes are noted, which lend support to Martin's suggestion that polar whistlers originate in lower latitudes and are then propagated into the polar regions by reflexion between the Earth and the lower ionosphere. The purpose of this communication is to describe observations showing that lightning sources in middle latitudes can give rise to whistlers heard at polar latitudes.

Simultaneous observations of whistlers have been made regularly since June 1958 at Scott Base, Ross Dependency, Antarctica, and at Dunedin and Wellington, New Zealand, situated 3,600 km. and 4,100 km. north of Scott Base, respectively. The geomagnetic latitudes of Dunedin and Wellington are 50.8° S. and 45.4° S. respectively. The times of occurrence of whistlers at these stations are normally reported to the nearest second.

A statistically significant association has been found between the occurrence of whistlers at Scott Base and of those reported from the stations in New Zealand. For example, for the first six months of 1960, during a total of 941 two-minute recording periods, 2,946 whistlers were heard at Wellington, while 1,548 were heard at Scott Base. Of these, 489 were found to be coincident. The number of coincidences expected to occur by chance is 48.5; thus there were 10.1 times more coincident whistlers than would be expected by chance. A similar analysis on a more limited series of results from Dunedin and Scott Base gave a ratio of actual coincidences to chance coincidences of similar magnitude (12.2). Statistical (chi-squared) tests applied to these results show that the correlation of occurrences of whistlers at these stations is highly significant.

Attempts have been made to examine the dispersion characteristics of coincident whistlers in order to determine whether these are identical at the three stations. A difficulty arises in obtaining readable spectrograms in that, when the field-strength of a whistler is strong at the New Zealand stations, it tends to be very weak at Scott Base, and vice versa. However, I have succeeded in obtaining readable spectrograms of long whistlers occurring at all three stations at 08h. 36m. 11s. U.T. on April 7, 1959. (The pattern of atmospherics occurring during a few seconds on either side of this time was used to obtain an accurate comparison of times.) At each station the whistler, which was swishy in character, was preceded by a loud atmospheric of the type classified as a 'bonk' by Morgan and Dinger⁴; on analysis, this bonk was identified as the initiating atmospheric. It had an unusually complex structure, indicating that multiple lightning discharges had taken place at 20–30 millisecc. intervals during a total time of 0.19 sec.

The dispersion analysis was carried out using an 11-channel comb-filter analyser, the filter frequencies f being arranged to give equal increments of $f^{-1/2}$ between channels, so that dispersion curves obeying the Ekersley-Storey approximation⁵ would be straight lines. The times of first and last observable response for each channel (starting and finishing times) are given in Fig. 1a and Fig. 1b respectively, time being measured from the commencement of the initiating bonk. The dispersion lines shown in Fig. 1a refer to the commencement of the bonk, and those in Fig. 1b refer to its end. Although the starting times at these three stations do not agree well, nevertheless, apart from the two exceptions, discussed below, the agreement of the finishing times is within the accuracy of determination of times from the spectrograms (normally about ± 0.02 sec.). These points closely describe a whistler component of dispersion $164 \text{ sec.}^{1/2}$, arising from the last component in the multiple lightning discharge.

An analysis of the wave-forms of the initiating bonk, as recorded at the three stations, suggested that the lightning-source was $1,100 \pm 200$ km. distant

Fig. 1. Dispersion characteristics of whistlers apparently arising from the same source, as recorded at Scott Base (S), Dunedin (D), Wellington (W), Stanford (T) and Seattle (X). The northern hemisphere times have been adjusted as described in the text. (a) Starting times; (b) finishing times

from both Wellington and Dunedin, and $4,350 \pm 300$ km. from Scott Base, that is, in the vicinity of lat. 38° S., long. 163° E., in the middle of the Tasman Sea. The New Zealand Meteorological Service has kindly supplied the information that a vigorous depression had its centre at lat. 39° S., long. 163° E., at 0600 U.T. on the day in question. This centre had moved to lat. 40° S., long. 165° E., by 1200 U.T. Thunderstorms and cumulo-nimbus clouds reaching altitudes of 20,000 ft. were reported by ships and aircraft in the area at this time. The synoptic weather charts indicate that this was the only likely thunderstorm area for some thousands of miles around. Therefore it appears to be reasonably certain that this region, at a geomagnetic latitude of about 43° S., gave rise to the whistler heard at Scott Base.

Sonagrams of short whistlers recorded at Stanford and Seattle, U.S.A., which apparently arose from the same source, have been kindly supplied by Mr. L. H. Martin, of Stanford University. The geomagnetic latitudes of these stations are 43.7° N. and 53.6° N. respectively. Both sonagrams show multiple component structure. The first components are well defined, especially on the Stanford record, but in both cases there is no clearly distinguishable last component because of high noise-level from local atmospherics. The initiating atmospheric was readily identified with that found on the southern hemisphere spectrograms. A time correction of 0.04 sec. was made, to allow for the time of propagation of the atmospheric from its source to the west coast of the United States. The times thus corrected were then doubled to permit direct comparison with the southern hemisphere data. This is shown in Fig. 1a. It will be seen that the Stanford starting times agree well with the Wellington times for frequencies between 4.3 and 7.3 kc./s., and describe a whistler component of dispersion $133 \text{ sec.}^{1/2}$ arising from the initial lightning discharge. On the other hand, the Seattle starting times are consistent with two of the three Scott Base starting times and the 3.85 kc./s. response at Wellington, indicating a whistler component of dispersion $141 \text{ sec.}^{1/2}$. The lowest-latitude stations in each hemisphere (Stanford and Wellington) have thus recorded an earlier

whistler component than the higher-latitude stations. The explanation of this may involve consideration of the terminal latitudes of the paths along which the various components were propagated through the outer ionosphere. The anomalous lateness of starting times at Dunedin is attributed to the exceptionally high noise-level there at that time.

In view of the way in which results from the various stations in both hemispheres correlate, and also in view of the multiple structure revealed by the Stanford and Seattle sonagrams, it seems reasonable to attribute the later finishing times at Wellington for frequencies of 4.85 and 5.5 kc./s. to the reception there of an additional component which was not recorded at Dunedin or Scott Base because of higher noise-levels at these two stations.

An extension of the dispersion analysis of the Wellington whistler showed no sign of a nose frequency up to 14.6 kc./s., the highest frequency at which there was a useful response. On the dipole representation of the geomagnetic field, this implies that the path of highest latitude for this whistler must have terminated below 60° geomagnetic latitude; if the nose frequency were one-half of the minimum gyrofrequency over the path, the maximum terminal latitude would be less than 55° . Since the nose frequency is likely to be at least 20 kc./s., the maximum terminal latitude is in fact likely to be less than 53° . Following an alternative line of reasoning, that of comparing the measured dispersion values with an empirical curve of the variation of dispersion with latitude given by Alcock⁴, a maximum terminal latitude of about 51° is inferred. The general agreement between these two estimates of the maximum terminal latitude makes it reasonably certain that the whistler under consideration not only arose from a source in middle latitudes, but also was indeed a true middle-latitude whistler, being propagated through the outer ionosphere along paths which terminated in middle latitudes. Reception of this whistler at the polar station of Scott Base would therefore imply a final stage of propagation underneath the ionosphere for more than 2,800 km.

This work forms part of the radio research programme of the Dominion Physical Laboratory. I am grateful to Prof. R. A. Helliwell of Stanford University for his assistance in providing equipment, and to the Antarctic Division, Department of Scientific and Industrial Research, New Zealand, for operating the Scott Base whistler equipment.

PHYSICS

Simultaneous Application of Townsend and Streamer Theory

RECENTLY conductivity current measurements up to the sparking potential have been carried out in hydrocarbon gases which can be interpreted if it is assumed that Townsend and streamer processes act simultaneously.

A sample measurement for isopentane is shown in Fig. 1. At $E/p = 300$ V. cm.⁻¹/mm. mercury, $p = 3$ mm. mercury, the d.c. ionization current was measured, by successive reduction of i_0 , over more than eight decades of amplification, without any sign of a deviation from the normal α slope, up to the sparking voltage of 990 V. which occurred at $d = 1.1$ cm. The last slope was obtained with 10 electrons leaving the cathode per second and this type of measurement has often been repeated and confirmed.

Fig. 1. Ionization current, i , as a function of gap distance, d , showing large multiplication possible in isopentane without apparent deviation from a normal α slope. Spark occurred at 990 V., $d = 1.1$ cm.; $E/p = 300$ V. cm.⁻¹ mm. Hg.⁻¹, $p = 3$ mm. Hg., $\alpha = 17.9$ cm.⁻¹. —○—○—, Experimental curve; — — —, estimated α curve, Richter (ref. 1); - - - - -, estimated α curve, Heylen; ×—×—×—, calculated values according to equation (3)

By monitoring the pulse shape of the ionic component of individual avalanches, it has been observed¹ that the number of charge carriers (n) increases less than $\exp(\alpha x)$ if n surpasses $N = 10^4$. The space charge field of the positive ions is held responsible for the reduction of the ionization of the advancing electrons and is comparable to the applied field; we are thus entering the streamer regime. It was found (for ether, a gas exhibiting an extremely low γ coefficient) that for $n \gg N$, Townsend's α coefficient could be expressed as:

$$\alpha(n) = \alpha (1 - B \ln n/N) \quad (1)$$

in which $B = 0.065$. From this, the charge multiplication factor was evaluated as:

$$x - x_N = \frac{1}{\alpha} \left\{ \frac{1}{1 - B \ln n/N} - \frac{1}{B} \ln(1 - B \ln n/N) - 1 \right\} \quad (2)$$

in which $N = \exp(\alpha x_N)$. The reduction from the normal α slope, according to equation (2), is shown in Fig. 1 (dashed line), and does not agree with the observed data. The discrepancy can be cleared up if it is

assumed that Townsend's secondary mechanism is operating simultaneously with the streamer inducing space charge reduction of Townsend's primary process. This can be taken into account by using the generalized Townsend equation:

$$i_x = i_0 \frac{\exp(\int \alpha dx)}{1 - \gamma (\exp(\int \alpha dx) - 1)} \quad (3)$$

in which $\exp(\int \alpha dx)$ can be found from Fig. 1 (dashed line). An estimate of γ can be obtained by making equation (3) fit the experimental curve. Thus, for $\gamma = 4.3 \times 10^{-8}$, a normal α slope would be recorded up to $d = 0.9$; for longer gaps, an upcurving would occur and the Townsend criterion for breakdown would be reached at $d = 0.98$, which is not in agreement with experiment.

From previous work² it has been surmized that for normal hydrocarbons, little space charge distortion occurs until $n \gg N = 10^7$, and from Richter's data¹ an equally good fit to $\alpha(n)$ can be obtained for $B = 0.2$. Substitution of this value into equation (2) yields the curve as shown in Fig. 1 (dot-dashed line). Combining this with equation (3) yields $\gamma = 10^{-8}$; the calculated values are shown (×). It is observed that no apparent deviation from a normal α slope occurs to within 5 per cent of the sparking distance, at which a faster than usual Townsend upcurving takes place.

The award of an Imperial Chemical Industries Fellowship by the University of London is gratefully acknowledged, and also a grant by the Central Research Fund. Thanks are due to Prof. M. W. Humphrey Davies for facilities provided.

The Nitrous Oxide Dosimeter

NITROUS oxide has been proposed¹ as a suitable material for the dosimetry of ionizing radiations over wide temperature- and pressure-ranges and with a wide variety of types of radiation. The basis for the yields quoted in ref. 1 was the measurement of radiation flux using ionization chambers or ferrous sulphate solutions. We have investigated the radiolysis of nitrous oxide and have compared the results of absolute measurements based on tritium as an internal source with measurements based on ferrous or ceric sulphate dosimetry, using cobalt-60 γ -rays or 4-MeV. X-rays as external sources.

It has been found that good agreement between the two methods is obtained provided the irradiations are done in vessels with internal diameters greater than about 15–20 mm. As the internal diameter decreases, the yields of all products, based on ferrous dosimetry, increase in a manner reminiscent of the increase in $G(\text{Fe}^{2+})$ from the ferrous sulphate dosimeter in vessels of a few millimetres diameter^{2,3}.

The products measured were nitrogen, oxygen and the oxides of nitrogen ($\text{NO} + \text{NO}_2$). Previous workers^{1,4} have used liquid nitrogen to separate the volatile and non-volatile constituents of the irradiated gas, but since in this technique reactions occur in the traps which can cause serious errors in the yields of oxygen and oxides, in this work the constituents were not separated. Gas chromatography was used for nitrogen and oxygen analyses, and the oxides of nitrogen were determined spectrophotometrically as nitrite.

$G(\text{N}_2)$ was 11.0 ± 0.4 at ambient temperatures and is the average from all the types of radiation mentioned, weighted in favour of the tritium irradiations (for which $G(\text{N}_2)$ was 11.2 ± 0.2 and 11.3 ± 0.5 for two experiments).

The most reliable results are likely to be obtained if nitrogen alone is measured, since it is unaffected by trap reactions or other analytical complications, and its yield is also unaffected by foreign gases such as hydrogen or methane, both of which markedly reduce the yields of oxygen and oxides of nitrogen, or by traces of water, which affects the relative proportions of oxygen, nitric oxide and nitrogen dioxide.

A more detailed account of this work will appear elsewhere.

The Wake of a Moving Drop

TWO-DIMENSIONAL flow behind bluff symmetrical obstacles has received the attention of fluid dynamicists for more than half a century. Considerations of the Kármán vortex-street afford an excellent example of the agreement between theoretical and experimental results. Three-dimensional wakes have been investigated intensively, but are less tractable as they do not exhibit the same uniformity or periodicity as the two-dimensional vortex-trails.

Practical considerations have been an important factor in confining most investigations to phenomena associated with the relative motion between a fluid and a rigid body. More recently, meteorological implications have prompted investigations into the mechanics of liquid drops falling through a quiescent gaseous medium such as air. Many engineering processes involving liquid-liquid phases secure contact through the dispersion of one phase as drops moving through a second liquid.

Telford, Thorndike and Bowen¹ described an experiment in which they determined the collision efficiency between equal-size drops about 150μ in diameter. Schotland² modelled the trajectories of cloud droplets of equal size by allowing steel spheres to fall through a sugar solution. The collision efficiencies obtained by these investigators support a wake collision process that may be important in the early stages of cloud drop growth studies. Studies of collisions between larger drops suggest a wake process is operative that may be of some importance

in determining the drop-size distribution observed in natural rain. Collisions between equal size drops, moving at the same terminal velocities, suggest a pressure gradient behind the leading drop which accelerates the trailing drop into contact. The time displacement relationships of a drop moving through a medium are directly dependent on the drag force, which in turn depends on the nature of the wake.

Liquid-liquid systems were used in the experiments described in this communication. The wakes of single drops of various organic liquids, moving through water at terminal velocity, were observed and recorded photographically. The wake pattern was rendered visible as a water-soluble dye was scrubbed from the moving drop.

Fig. 1 shows the wake pattern behind a drop of carbon tetrachloride (equivalent diameter 0.24 cm.) moving through quiescent water at 25°C. with a Reynolds number of 360. Fig. 2 shows the wake of the same drop after its energy has been dissipated, but before its identity has been lost through diffusion processes. There is a time-interval of 10 sec. between the two exposures.

The wake behind a drop moving through a liquid phase with Reynolds numbers up to some value, limited by drop oscillations, is characterized by two rows of vortex rings. These rings all move at the same acute forward angle with the line of fall of the drop. The almost perfect symmetry is evident in the wakes of all drops, regardless of the deviation from sphericity, in which there are no local oscillations. Larger oscillating drops result in the production of more energetic rings, but lack the symmetry of the smaller

Fig. 1. The wake behind a carbon tetrachloride drop falling through water at terminal velocity. Reynolds number 360. Photograph taken at an angle of 45° with the plane of the wake

CHEMISTRY

Organic Ion Flotation

In an earlier communication¹, a procedure for concentrating inorganic ions is outlined. It has been found now that it is possible to concentrate organic ions from aqueous solution by adding a surfactant collector, of opposite charge, suitably prepared to ensure the absence of micelles, and then, by the introduction of fine bubbles, floating the insoluble product to the surface where it collects in the froth, or preferably as a scum. The principle is the same as for inorganic ion flotation, but there is one important distinction. In inorganic ion flotation, because the ions are often polyvalent, the product between the ion and the collector having more than one hydrophobic centre, is highly insoluble and usually forms a scum very quickly. But organic ions are often univalent, and therefore the product, though still insoluble, sheds water less readily, and there is more tendency to form a stable froth. This can, however, be broken by blowing hot air on to it, though it is not desirable to destroy it completely. A residual froth bed should be left, upon which the concentrate can float. This becomes necessary as the uni-univalent product, which is really a salt, can sometimes dissociate again, if allowed to come into contact with bulk water. If the precautions mentioned in the previous communication are observed, excellent recoveries from very dilute solutions are obtainable. Furthermore, the remarkable degree of selectivity shown by the method in the case of inorganic ions, when starvation amounts of collector are added incrementally, is shown as well in the case of organic ions.

In order to avoid laborious organic analyses, much of the exploratory work was done with dilute solutions of dyes or indicators, usually of a concentration of about 0.01 gm./l. Such solutions could be decolorized completely, sometimes in a matter of minutes, the colour being collected in the froth. Some dyes, having both anionic and cationic centres, could be floated by either cationic or anionic collectors, depending on the pH, but others could only be floated by one type of surfactant.

The following experiment will illustrate the selectivity. 3 mgm. each of potassium indigo sulphate, congo red, methyl orange, bromphenol blue and phenolphthalein were freshly made up into a 400 ml. aqueous solution, and made slightly alkaline with ammonia to make the dyes anionic. This solution was put into a No. 4 sintered glass Buchner funnel. Solid lauryl pyridinium chloride was freshly dissolved in absolute alcohol (2.2 mgm./ml.) and was added in 1 ml. portions, followed by air blown gently through the sintered glass. The dyes were floated in the above order, the distinctive colour of each being clearly perceptible in the froth at each stage. After addition of about 7 ml. of collector, the solution was completely colourless. In a similar experiment, to which Lauth's violet, a cationic dye, had been added, the blue colour of it remained and could not be removed by a cationic collector. If, however, the solution was made slightly acid, pH 5, and α -sulpholauric acid added as a collector, the dye was removed by bubbling, leaving the solution colourless.

In working with dyes, it is advisable to use fresh solutions, as dyes have a tendency to form micelles, and old solutions may give misleading results. As it is

Fig. 2. The wake behind the same drop 10 sec. after the drop has passed

drops. Hu and Kinter², Johnson and Braida³, and Licht and Narasimhamurty⁴ report results on drop diameter-drop velocity relationships for carbon tetrachloride-water systems. These reports indicate that 0.32 cm. represents about the maximum size of a carbon tetrachloride drop that can fall through water without oscillation. This corresponds to a Reynolds number of about 900. In these experiments, the wake symmetry has been observed for drop-diameters and Reynolds numbers approaching these values.

Disturbances in the vortex sheet behind the drop are responsible for the shedding on alternate sides of the drop. The wake appears to be independent of gross oscillations of the drop. Any local oscillations or zig-zag motions of the drop as it passes through the disperse phase are not discernible. The work is being continued in liquid-liquid systems and extended to liquid-gaseous phases.

only ions which are collected, and as organic substances are usually weakly dissociated, the control of pH is very critical. As cationic collectors, the alkyl quaternary ammonium soaps, or the long-chain amines proved most suitable, and as anionic collectors, α -sulpholauric acid or its potassium salt proved most convenient. It is possible to recover the floated organic ion by a double decomposition reaction in a non-aqueous solvent, either benzene or alcohol, each procedure being determined by a knowledge of the chemistry of the species involved.

A number of organic ions, chosen at random, have been floated, establishing the generality of the method. These included picrate, gallate, tetraphenyl boron, and the alkaloids strychnine and brucine. This indicates that the method might be useful in collecting organic ions from natural products, especially as the carbohydrates are not likely to float. It has potential application in concentrating antibiotics and other valuable biological products which are ionizable.

Another possible use is in clarifying solutions. For example, a sugar solution that had been charred to a black molasses residue was dissolved in water to give a dirty brown solution. Using trimethyldodecylammonium chloride as a collector, the colouring matter was floated into the froth, leaving the solution almost colourless.

One of the difficulties in taking the fullest advantage of the selectivity shown by ion flotation in respect of organic ions is that the products are usually colourless, so that it becomes difficult to ascertain when one species is fully collected and the next is about to concentrate. It may become possible to overcome this problem by taking advantage of the large variety of dyestuffs. If these were to be placed in a series of relative floatability, it may be possible to find a dye just intermediate between the two species to be separated. On the introduction of a small amount of such a 'marker dye' into the solution, it would be possible to see when the collection of the first species is finished, by the first appearance of the dye colour in the froth.

Dipole Moments of Fluorine Monoxide and Sulphur Tetrafluoride

In setting up a teaching experiment on the dipole moments of gases, we recently took the opportunity to measure the temperature dependence of the polarization of fluorine monoxide (F_2O) and sulphur tetrafluoride (SF_4). The condenser comprised two concentric stainless steel cylinders similar to that described by Groves and Sugden¹. The capacity of the condenser was about 80 pF. and was measured with an accuracy of 1 part in 16,000 by a ratio-transformer bridge. The condenser was mounted in a cylindrical glass vessel which was immersed in the thermostat bath. Capacities were measured with the gases at atmospheric pressure over the temperature-ranges -78° to $+80^\circ$ C. for fluorine monoxide and -30° to $+80^\circ$ C. for sulphur tetrafluoride. The apparatus was calibrated with dry air free of carbon dioxide to eliminate the effect of stray capacity.

Fluorine monoxide was made by bubbling fluorine, diluted with nitrogen, through 2 per cent caustic soda solution²: sulphur tetrafluoride was obtained through the courtesy of Imperial Chemical Industries, Ltd. (Alkali Division).

The plot of total polarization against reciprocal temperature was not sufficiently accurate to permit extrapolation to infinite temperature. Values of the induced polarization were therefore estimated independently: 5 c.c./mole for fluorine monoxide and 12.5 c.c./mole for sulphur tetrafluoride. Straight lines drawn through these and the experimental points gave the following values of the dipole moments; the errors indicate maximum and minimum slopes of lines drawn through the estimated point at infinite temperature.

Fluorine monoxide $\mu = 0.4 \pm 0.1 D$ using $P_0 = 5$ c.c./mole; sulphur tetrafluoride $\mu = 1.0 \pm 0.1 D$ using $P_0 = 12.5$ c.c./mole.

The value for fluorine monoxide is much smaller than that of OH_2 (1.84 D) and is thus similar to NF_3 (0.2 D) the dipole moment of which is much smaller than that of NH_3 (1.5 D). Coulson³ suggests that the true bond moment of OH in water is 1.08 D in the

sense O^+-H . The lone pair moment in water must then be 3.19 D. If the same lone pair moment is assumed in fluorine monoxide on the grounds that the same angle indicates the same hybridization, then the true O—F bond moment is 2.9 or 2.3 D depending on the sense of the overall moment, 0.4 D.

Little can be said about sulphur tetrafluoride except that the dipole moment is consistent with the C_{2v} structure which has been proposed⁴, and which arises from a trigonal bipyramid (dsp^3 hybridization) when one of the three equatorial positions is occupied by the lone pair. It would, however, be equally consistent with the C_{3v} symmetry which would obtain if the lone pair occupied a polar position.

We are grateful to Dr. M. Fleischmann for his advice and to the Department of Scientific and Industrial Research for a grant to one of us (R. L.).

Gas-Flow Patterns in Fluidized Beds

A FLUIDIZED bed is sometimes used as a means of carrying out a chemical reaction between a gas and solid particles. In gas-fluidized beds, 'bubbles' form and there is considerable interest in the part played by these in gas/solids in contact. It has been suggested, for example, that some of the gas rises through the bed in the form of bubbles and effectively bypasses the solid particles¹. Several investigators¹⁻⁷ have made various indirect measurements and have concluded that back-mixing of the gas occurs. These processes are important in estimating reaction-rates. So far as we are aware, no one has hitherto observed directly gas-flow patterns within the bed.

We have recently measured directly local gas velocities in a fluidized bed under special conditions.

Fig. 1

The bed was 12 in. wide and 15 in. deep, but only 1 in. from back to front so that it was effectively two-dimensional. The containing walls were made of 'Perspex', and within them 0.46-mm. diameter glass spheres were fluidized by air. Typical 'bubbles' formed and with rear illumination they could be seen in some detail. Near the bottom of the bed a number of small holes were drilled through the wall and into any of these a fine stream of nitrogen peroxide could be injected. With suitable illumination the progress of this coloured tracer stream could be followed through the bed, and by interrupting it periodically, velocities could be measured. The tracer flow-rate was less than 0.5 per cent of the fluidizing gas-rate so that its overall effect was negligible.

The accompanying photographs (Fig. 1) were selected from a film taken at 100 frames/sec. They show events at approximately 0.2-sec. intervals. The air velocity based on the empty cross-section was 0.9 ft./sec. (about 10 per cent above the minimum fluidization velocity) and the 'bubble' velocity is seen to be about 1.3 ft./sec. but it is increasing up the bed. The tracer stream velocity was about 1.6 ft./sec. and gas is seen to be continuously flowing into the void. Other photographs show the tracer flowing into the void as a jet, but it quickly loses its identity and becomes mixed with air. From a 'bubble' filled with this diluted nitrogen peroxide, we have seen the gas diffuse through the surrounding particles, mostly through the top of the void. Thus, gas in the 'bubble' is by no means isolated from the bulk of the bed. Back mixing of the gas by reverse flow does not generally occur, at least during gentle fluidization, but occasionally, when the solids are very violently mixed, they carry tracer gas with them against the general direction of flow; but this is a rare event.

Evidence for a Nitric Oxide Complex with Cupric Fluoride

ALTHOUGH it has been recognized for some time that nitric oxide and cupric chloride or bromide combine in non-aqueous solvents to form nitrosyl complexes¹, the composition of these has only recently been determined². The deep blue colour is due to the covalent $\text{CuX}_2 \cdot \text{NO}$ (possibly solvated): this compound dissociates into colourless ions:

and this has been responsible for erroneous structures suggested for the complexes. Unsuccessful attempts have been made to prepare nitrosyl complexes in alcoholic solution from other cupric salts, including the fluoride³. Recently, a study of the variation of dissociation constant of the cupric chloride nitrosyls as a function of the dielectric constant of the alcohol has been made⁴: some results are shown in Table 1.

Table 1. DISSOCIATION CONSTANTS FOR $\text{CuCl}_2 \cdot \text{NO}$ IN ALCOHOLS

Solvent	K (23° C.)
Methanol	4.2×10^{-2}
Ethanol	5.4×10^{-3}
<i>n</i> -Propanol	5.3×10^{-4}
<i>n</i> -Butanol	2.0×10^{-5}

The decrease in dissociation is much greater than would be predicted by the Born equation if dielectric constant were the only factor involved. Thus it appeared that if a nitrosyl could be prepared from cupric fluoride it would only be stable in an alcohol such as *n*-butanol. Using anhydrous cupric fluoride, a violet colour is indeed obtained when nitric oxide is bubbled into the butanol solution, and the absorption of the gas is greater than it is in the absence of cupric salt. The colour fades rapidly, and a white precipitate containing copper and fluoride forms. A similar result is obtained with hydrated cupric fluoride. If the solvent used is *t*-butanol, the violet colour is quite stable, and no precipitate forms for at least 10 min. Addition of hydrofluoric acid has no effect on the optical spectrum of the *t*-butanol complex; but when a trace of the acid is added to any other alcohols containing either anhydrous or hydrated cupric fluoride, and nitric oxide bubbled through, the deep blue nitrosyl colour forms immediately and is quite stable. Fig. 1 shows the close resemblance of the absorption spectra of some of the fluoride nitrosyls to the cupric bromide nitrosyl formed in *n*-butanol.

Fig. 1. Optical absorption spectra of the cupric fluoride nitrosyls in alcohols
1, Ethanol; 2, *n*-butanol; 3, *t*-butanol; 4 (dotted line), $\text{CuBr}_2.\text{NO}$ in *n*-butanol, shown for comparison; 5, *n*-propanol; 6, CuF_2 hydrate in *n*-propanol

There is a gradual shift in the position of the absorption maximum of the complex as the solvent is changed. Table 2 shows wave-lengths of maximum absorption for the three nitrosyl complexes in alcohols⁴.

Table 2. POSITION OF ABSORPTION MAXIMA

Solvent	$\text{CuF}_2.\text{NO}$	Max. $\lambda(\text{m}\mu)$ $\text{CuCl}_2.\text{NO}$	$\text{CuBr}_2.\text{NO}$
Ethanol	499	550	570
<i>n</i> -Propanol	551	550	570
<i>n</i> -Butanol	551	550	565
<i>t</i> -Butanol	475	—	530

Methanol is the only alcohol examined so far in which the nitric oxide-cupric fluoride cannot be formed in the presence of hydrofluoric acid: only a transient yellow coloration is obtained. The nitrosyl solutions are not stabilized by lithium or sodium fluorides as they are by hydrofluoric acid. The role of the acid is merely to depress the ionization of the covalent nitrosyl.

Separation of Amino-acid Mixtures on Sulphonated Polystyrene Resin-loaded Papers

THE high resolving powers of columns of cross-linked sulphonated polystyrene resins when applied to the separation of mixtures of amino-acids has been demonstrated by the classic work of Moore and Stein¹ and afterwards by other workers^{2,3}.

For rapid qualitative separations a paper chromatographic technique offers definite advantages. In addition to its simplicity of operation is the ability to: (a) detect the separated zones on the paper, thus rendering elution unnecessary; (b) develop several chromatograms side by side; (c) record simply the rate of movement of a zone relative to that of the solvent front; and (d) combine two separate developments on the same sheet of paper as a two-dimensional chromatogram.

The advent of the ion-exchange papers has made it possible to realize the advantages of both ion-exchange method and paper chromatographic technique. The object of the work presented here is to compare in a purely qualitative manner the resolving powers of ion-exchange resin in column and paper form.

Separations of the amino-acids on ion-exchange cellulose papers have previously been described⁴, as also have some limited separations on ion-exchange resin-loaded papers, but so far the resolution on the latter materials has not approached that possible on resin columns^{5,6}.

The most satisfactory results were obtained on a paper (patent applied for), made specially in these Laboratories, containing 'Zeokarb 225 (WR 1.5-2.0)' resin in a form particularly suited to the requirements of chromatographic separations.

A number of other sulphonated polystyrene resin-loaded papers were also investigated, including some commercially available papers, but were found to be of limited use for critical separations.

1 $\mu\text{gm.}$ of each of sixteen amino-acids was applied as separate spots to a sheet of the resin-loaded paper which had previously been equilibrated with 0.2 *M* pH 3.1 buffer¹. The equilibrated paper was carefully blotted to remove excess liquid and the amino-acids were applied to the wet paper. The chromatogram was developed in the 0.2 *M* pH 3.1 buffer by a descending technique for a period of 90 min., after which the dried paper was sprayed with a 0.2 per cent solution of ninhydrin in acetone containing 0.1 per cent collidine⁷. The pattern of amino-acids which resulted is illustrated in Fig. 1.

A separation of amino-acids on a column of 'Zeokarb 225 (WR 1.5-2.0)' through 200-mesh resin, developed according to the Moore and Stein technique, is illustrated in Fig. 2.

10 mgm. of amino-acid mixture was applied to the column, and the complete run took 50 hr.

Fig. 1

Fig. 2

Although the gradient elution of the column technique has been replaced on the paper by a simple elution with a single buffer, the sequences on the two forms of the resin, with the possible exception of the basic group of amino-acids, are comparable, and such a comparison is made in Table 1.

Table 1. A COMPARISON OF THE SEQUENCE OF AMINO-ACIDS ON COLUMN AND PAPERS CONTAINING 'ZEOKARB 225' RESIN

Sequence of decreasing rate of movement	
Sulphonated polystyrene resin column (4.5 per cent cross-linked). Developed according to Moore and Stein (ref. 1)	Sulphonated polystyrene resin-loaded paper. Developed in 0.2 M pH 3.1 buffer
Asp	Asp
Thr	Thr
Ser	Ser
Pro	Glu
Glu	Pro
Gly	Gly
Ala	Ala
Val	Val
Leu	Cys
Tyr	Leu
Phe	Phe
Orn	Tyr
Lys	Orn
His	Lys
Arg	His
	Arg

It may be seen that some differences in sequence on the two forms of the resin occur and that these are mainly associated with a reversal of the tyrosine-phenylalanine and the proline-glutamic acid groups. These differences can probably be attributed to the influence of the cellulose matrix on separations on the resin-loaded papers.

With the exception of the above differences the high resolution of the column technique is matched by that of the paper, and because the latter can be achieved without elution the time required for such a separation is considerably reduced.

A property of the ion-exchange paper which has not been used in the above separation is that associated with the cellulose matrix itself when the ion-exchange characteristics are suppressed. Separations describing the use of a new two-dimensional technique in which ion-exchange and 'partition' techniques are combined on the ion-exchange cellulose papers have been described^{4,8}.

In the case of the sulphonated polystyrene resin-loaded paper the separation of the amino-acids achieved under ion-exchange conditions ideally combines with that achieved under 'partition' conditions. This is because the sequences of amino-acids produced by the two sets of conditions are very different. This is a point of difference from the ion-exchange cellulose papers and is due to the different matrixes associated with the two types of exchanger. A separation illustrating the new two-dimensional method is shown in Fig. 3.

Fig. 3

In this the first development was carried out with 0.2 M pH 3.1 buffer on the dry sodium form of the paper and the second development in *m*-cresol - 0.3 per cent ammonia. The ammonia solution, present in the bottom of the chromatography tank, assured a suppression of the effect of ion-exchange characteristics by producing an anionic form of the amino-acids. The paper was equilibrated over the ammonia for 1 hr. before introduction of the second solvent. The complete separation was achieved in a single day.

The most striking feature of the separation illustrated in Fig. 3 is the absence of amino-acid spots along the diagonal of the paper through the origin. A diagonal distribution of spots and consequently a lack of high resolution are common features of many conventional two-dimensional chromatograms. By completely breaking up such a distribution and by adding to the high resolving power of the resin itself the new two-dimensional technique on sulphonated polystyrene resin-loaded paper probably provides the highest degree of resolution of amino-acids yet obtained in a single chromatographic analysis.

A fuller account of the analysis of amino-acid mixtures on different types of ion-exchange papers is being prepared and will be published elsewhere.

I wish to thank the directors of W. and R. Balston, Ltd., for permission to publish this communication.

BIOCHEMISTRY

Hexosamine Synthesis by Cell-free Extracts of Various Bacteria

AN enzyme system catalysing the synthesis of glucosamine-6-phosphate from glutamine and fructose-6-phosphate or glucose-6-phosphate has been demonstrated in *Neurospora crassa*^{1,2}, rat liver^{2,3} and *Escherichia coli*³. Ghosh *et al.*³, who purified the enzyme from these various sources and studied its properties, have called it L-glutamine-D-fructose-6-phosphate transamidase. We have determined transamidase activity in fresh, cell-free extracts of *Bacillus cereus*, *Micrococcus lysodeikticus*, *Aerobacter aerogenes* and *Escherichia coli*. Results indicate that, for a given weight of cells, activity is higher in Gram-positive than in Gram-negative bacteria, and for a given organism, activity increases markedly during the lag and early exponential phases of growth, but decreases during the stationary phase. The high transamidase activity associated with dividing cells is probably related to the synthesis of cell-wall basal structure⁴, which contains amino-sugars. During these investigations, using a system with standard conditions of pH, substrate concentrations and reaction time at 37°, it was found that the amount of glucosamine-6-phosphate synthesized rarely exceeded 25 per cent theoretical, and frequently was not proportional to enzyme concentration when different volumes of the same cell extract were tested in parallel. An attempt was made to explain these findings.

Cell-free extracts were prepared from *Bacillus cereus* vegetative cells suspended in water (20–50 mgm. dry weight/ml.) by disintegration with ballotini beads in a Mickle disintegrator⁵ and centrifugation of the

Fig. 1. Synthesis of hexosamine by an extract of disintegrated *Bacillus cereus* cells. Reaction mixtures (1 ml.) contained 0.3 M phosphate buffer, pH 6.5 (0.2 ml.), extract (from 18 mgm. dry weight cells) and substrates as follows (μmoles):

	(a)	(b)	(c)	(d)
Glucose-6-phosphate	20	20	40	40
Glutamine	20	50	40	100

Samples (0.1 ml.) removed immediately and at intervals during incubation at 37° were acidified with acetic acid, heated at 100° for 2 min. and diluted to 3 ml. Hexosamine was determined in the supernatant fluids (1 ml.)

Fig. 2. Comparison of transamidase and deaminase activities in an extract of *Bacillus cereus* cells. Reaction mixtures (0.5 ml.) contained 0.4 M phosphate buffer (0.2 ml.), extract (from 6 mgm. dry weight cells) and other additions as follows (μmoles):

	(a)	(b)	(c)	(d)
Glucose-6-phosphate	15	—	15	15
Glutamine	25	—	25	—
Glucosamine-6-phosphate	—	4.3	—	4.3
Ammonium chloride	—	—	375	375
Versene	—	—	15	15

Samples (0.1 ml.) removed and treated as in Fig. 1

homogenates. The activity of an extract prepared in this way was equivalent to that obtained from the same weight of cells disintegrated in a Hughes press⁶. The rates of formation of hexosamine in the presence of extract and various amounts of glucose-6-phosphate (extract contained phosphoglucose isomerase³) and glutamine at pH 6.5 are shown in Fig. 1. Control tubes containing heat-inactivated extract and substrates were included, and hexosamine was determined in tests and controls by the method of Rondle and Morgan⁷ modified by the use of carbonate-bicarbonate buffer⁸. In all cases hexosamine increased to a maximum not exceeding 25 per cent theoretical (based on amount of glucose-6-phosphate present) and then decreased. Similar results were obtained when reaction mixtures were buffered at pH 7.5. Apparently the low maximum yield of product was not due to enzyme inactivation during incubation since hexosamine was synthesized when glutamine was added to glucose-6-phosphate + extract + buffer preincubated for 1 hr. at 37°. Nor was destruction of substrates by glutaminase and phosphatase activities in the extract sufficient to explain the results. Loss of hexosamine-reacting material after the maximum had been reached was not due to formation of N-acetylhexosamine derivatives or incorporation into a larger molecule since no increase in hexosamine was found after hydrolysis with 6 N hydrochloric acid. Comb and Roseman⁹ purified and studied the properties of an enzyme in *Escherichia coli* which deaminated glucosamine-6-phosphate releasing fructose-6-phosphate and ammonia; the reaction was reversible. An enzyme with similar properties was present in extracts of the bacteria mentioned

Fig. 3. Effect of added glucosamine-6-phosphate on hexosamine synthesis in the presence of excess ammonium salt. Reaction mixtures (0.5 ml.) contained 0.4 M phosphate buffer, pH 7.5 (0.12 ml.), extract (from 14 mgm. dry weight *Bacillus cereus* cells), versene (15 μmoles), ammonium chloride (250 μmoles), glucose-6-phosphate (10 μmoles) and other additions as follows (μmoles):

Glucosamine-6-phosphate	(a)	(b)	(c)
Glutamine	20	20	—

Samples (0.1 ml.) removed and treated as in Fig. 1

above and its activity was maximal near pH 8.5 but appreciable at pH 6.5–7.5. Using the same amount of *B. cereus* cell extract at pH 7.5, the rate of disappearance of hexosamine from a reaction mixture containing glucosamine-6-phosphate was compared with the rate of hexosamine synthesis in the presence of glucose-6-phosphate and glutamine (Fig. 2). Results indicated that the apparently restricted synthesis of hexosamine was due to destruction of the product by deaminase activity. Attempts were made to inhibit the degradation reaction. Deaminase activity was markedly reduced by a mixture of disodium ethylenediamine tetraacetic acid (versene) ammonium salt in excess and glucose-6-phosphate, whereas transamidase activity increased in the presence of ammonium salt + versene (Fig. 2) and was proportional to the volume of extract added when reaction mixtures were incubated for 15–30 min. at 37°. A small synthesis of hexosamine occurred when extract was incubated with glucose-6-phosphate and excess ammonium salt at pH 7.5, but this did not account for the increased transamidase activity. However, it was shown that deaminase activity was not completely inhibited under these conditions, by measuring transamidase activity in the presence and absence of added glucosamine-6-phosphate; inhibition was less when the concentration of hexosamine in reaction mixtures increased (Fig. 3).

Under the conditions described, the direct, accurate measurement of L-glutamine-D-fructose-6-phosphate transamidase activity in crude bacterial extracts is not possible owing to the presence of glucosamine-6-phosphate deaminase. Methods for the purification of the two enzymes have been described by other workers^{3,9}, and it is possible that quantitative separation of the transamidase could be achieved. However,

the instability of the enzyme^{1–3} makes this a difficult problem.

Heterogeneity of Liver Lecithin isolated by Chromatography on Silicic Acid Columns

THE recent report by Collins¹ of the heterogeneity of lecithin labelled with phosphorus-32 is supported by results obtained by us as part of an investigation of the effect of ethionine on the incorporation of phosphorus-32 into the liver phosphatides of rats. This will be reported in full elsewhere but an experiment on normal rats, which is relevant to the work of Collins, is described here.

Three rats were each injected intraperitoneally with 4 μc. of labelled orthophosphate. Three hr. later, the rats were killed and their livers were removed. The lipids from the combined livers were extracted and freed from water-soluble components containing radioactive phosphorus by a procedure similar to that described by Fishler and Chaikoff², except that the ether extract of the liver lipids was washed with 0.1 N hydrochloric acid and 0.01 N sodium chloride³, rather than with a solution of unlabelled sodium phosphate.

The total phosphatides were first separated from the other lipids in the extract on a silicic acid column⁴ and were then fractionated on a second column of silicic acid using mixtures of chloroform and methanol as the eluting solutions^{5,6}. The silicic acid columns were 'aged' before use as described by Gray and Macfarlane⁷ to minimize breakdown of acetal phosphatides. The fractions from the column were analysed for choline, amino-nitrogen and inositol, as well as for total phosphorus and esterified fatty acids. The fractionation, on the basis of the phosphorus analyses, is shown by the elution curve in Fig. 1. The main component eluted by the 4:1 chloroform/methanol mixture is a mixture of serine and ethanolamine phosphatides, and the main component eluted by the 1:1 chloroform/methanol mixture is lecithin. Inositol phosphatide is eluted immediately before the lecithin and, in this particular fractionation, is incompletely separated from it. This pattern of elution of rat liver phosphatides is the same as that described by Hanahan *et al.*⁸.

The specific activities of the successive fractions collected from the column during the elution of the lecithin component are also shown in Fig. 1. There is a continuous rise in the specific activity as the lecithin is eluted. This increase in specific activity could be caused by contamination of the lecithin with the components which either preceded or followed

Fig. 1. Separation of liver phosphatides on a column of silicic acid (Mallinckrodt's analytical reagent, 100 mesh). Load, 25 mgm. per gm. silicic acid. Flow-rate, 0.5-1 ml. per min. The eluting solvents were mixtures of chloroform and methanol in the ratios shown in the figure. 10 ml. or 20 ml. samples of eluate were collected. —●—, phosphorus concentration in µgm./ml.; —○—, counts/min./µgm. phosphorus

it from the column. However, the specific activity of the inositol phosphatide fraction, measured in tube 48, was 12.0 and that of the uncharacterized component eluted immediately after the lecithin, measured in tubes 80-85, was 6.3. Such an explanation is therefore unlikely. A similar rise in specific activity, not shown here, was observed as the mixed serine and ethanolamine phosphatides were eluted.

The combined fractions in the tubes 50-55 (fraction A) and in tubes 60-72 (fraction B) from the lecithin peak were examined further. Acetal phosphatides, measured by the method of Gray and Macfarlane⁷, formed 3 per cent of the total phosphatides in fraction A and were absent from fraction B. The phosphorus/choline/esterified fatty acid ratio in fraction A was 1/0.97/1.90 and that in fraction B was 1/0.92/1.94. After methanolysis of the fractions, the methyl esters of the fatty acids were analysed by gas-liquid chromatography (Table 1).

Table 1. PERCENTAGE FATTY ACID COMPOSITION OF LECITHIN SUB-FRACTIONS A AND B

Fatty acid (trivial names)	No. of carbon atoms and double bonds	Retention time relative to stearate	Fraction A	Fraction B
Myristic	14-0	0.204-0.215	—	0.46
—	15-0	0.310-0.314	—	0.42
Palmitic	16-0	0.456-0.461	23	33.2
Palmitoleic	16-1	0.515-0.520	0.72	1.98
—	17-0 (?)	0.665-0.690	0.72	0.68
—	17-? un.	0.830-0.833	0.50	—
Stearic	18-0	1.000	44.4	16.3
Oleic	18-1	1.10-1.11	4.53	15.4
Linoleic	18-2	1.34-1.35	5.81	21.2
Arachidonic (?)	20-4 (?)	3.52-3.56	20.2	10.3

The fatty acids in fractions A (tubes 50-55) and B (tubes 60-72) were converted to the methyl esters by refluxing the fractions with 1.3 N hydrochloric acid in a dry methanol/benzene mixture for 2 hr. The methyl esters were separated on the Pye argon gas chromatograph at 175°C. and with an argon flow-rate of 50-60 ml./min. The stationary phase was the adipate ester of polyethylene glycol (10 per cent on acid-washed, 100-120 mesh, 'Celite'). The

relative retention time for the methyl ester of arachidonic acid on this column is normally 3.22. The identification of the C20-4 component as arachidonic acid is probably correct, however, since its relative retention time on a second column with 'Apiezon L' as stationary phase was 1.48, the usual value for the methyl ester of arachidonic acid. Under the above experimental conditions the determination of unsaturated acids with C22 and upwards is unsatisfactory and values for these acids are not included in Table 1. They were present in both fractions as minor components, the amounts in fraction A being greater than those in fraction B.

The results show marked differences in the fatty acid composition of the two fractions. For example, stearic and arachidonic acids are the main saturated and unsaturated acids in fraction A, whereas in fraction B the main saturated acid is palmitic acid and the main unsaturated acid is linoleic acid. The combined percentage of mono- and poly-saturated fatty acids is greater in fraction B than in fraction A. This pattern has been confirmed in further work.

As prepared by silicic acid chromatography, rat liver 'lecithin' therefore appears to be heterogeneous. Its heterogeneity can be expressed both in terms of differences in fatty-acid composition and in the rate of turnover of the 'lecithin' phosphorus.

Transforming Activity of Deoxyribonucleic Acid labelled with 5-Bromouracil

Ephrati-Elizur and Zamenhof¹ demonstrated that deoxyribonucleic acid from *Bacillus subtilis* grown in 5-bromouracil-supplemented media contained this analogue and retained its transforming activity. It thus became important to determine the specific transforming activity for purified fractions of each of the three molecular variants of deoxyribonucleic acid which can be extracted from organisms treated with 5-bromouracil: (1) unlabelled deoxyribonucleic acid

molecules, and those in which 5-bromouracil has been substituted for thymine in (2) one strand ('unifilar' labelling) or in (3) both strands ('bifilar' labelling) of the double helix. Two strains of *Bacillus subtilis*, wild type² and uracil-requiring strain 265 (kindly supplied by Dr. R. Guthrie), served as the donors of deoxyribonucleic acid. These were first grown with aeration at 37° C. for 4 hr. in nutrient broth supplemented with thymidine (10 µgm. per ml.), and afterwards incubated for 2-3 generations in minimal broth² containing 2-5 µgm. 5-fluorodeoxyuridine (serving as the thymidylate synthetase inhibitor³), 25 µgm. uridine (to suppress the conversion of 5-fluorodeoxyuridine to 5-fluorouracil and 5-fluorouridine) and 50-250 µgm. 5-bromodeoxyuridine per ml. Under these conditions, similar to those first employed for *Escherichia coli* by Lorkiewicz and Szybalski⁴, the molar ratio of 5-bromouracil to 5-bromouracil + thymine (5-bromouracil substitution) in non-fractionated deoxyribonucleic acid varied from 35 to 61 per cent as assessed by chromatographic determination⁵.

Employing another procedure, with aminopterin as inhibitor of thymidylate synthesis, the wild-type strain was reported to incorporate essentially no 5-bromouracil, while analogue substitution in strain 265 was 12 per cent¹. Highly polymerized deoxyribonucleic acid was isolated from cells lysed by lysozyme (100 µgm./ml.) and sodium laurate (5 per cent), deproteinized by the chloroform-butanol or phenol⁶ procedures and freed of ribonucleic acid by

Fig. 1. Buoyant density distribution of deoxyribonucleic acid (*B. subtilis* transforming principle) centrifuged for 72 hr. at 35,000 r.p.m. in the SW-39L rotor (broken line) or for 20 hr. at 44,770 r.p.m. in the analytical centrifuge, 'Spinco' model E equipped with ultra-violet optics (ref. 6) (dotted line), and the specific transforming activities of the same fractions, all adjusted to similar optical density, and tested with indole- (○) (two experiments), methionine- (Δ) and histidine-16- (▲) requiring recipient strains of *B. subtilis* (0.1 µgm. deoxyribonucleic acid, 10⁸ cells per ml. medium). Each point corresponds to a 3- or 9-drop fraction (30-90 µl.), out of the total 3 ml. used for centrifugation. We are indebted to Mr. Carl Schildkraut of the Department of Chemistry, Harvard University, for the analytical centrifuge runs and to Drs. J. Marmur and J. Eigner and Prof. P. Doty for the help and hospitality extended to one of us (W. S.) during the performance of these determinations.

Fig. 2. Buoyant density distribution of deoxyribonucleic acid labelled with 5-bromodeoxyuridine, extracted from *B. subtilis* grown for approximately two generations on 5-bromodeoxyuridine, 5-fluorodeoxyuridine, uracil-supplemented minimal medium. For explanation of curves, see Fig. 1. The left peak (1.776 gm. × cm.⁻³) corresponds to 70.5 per cent 'bifilar' 5-bromodeoxyuridine labelling while the centre peak (1.742 gm. × cm.⁻³) represents the 'hybrid' molecule (70.5 per cent 'unifilar' labelling). Since guanine + cytosine comprise 42 moles per cent of *B. subtilis* deoxyribonucleic acid bases (ref. 11), overall incorporation of bromouracil into the deoxyribonucleic acid represented by these density peaks was calculated to amount to 46.7 per cent, which figure agrees with the results of chromatographic 5-bromouracil determinations (ref. 5) on non-fractionated deoxyribonucleic acid. The small peak on the right (1.702) probably corresponds to deoxyribonucleic acid free of 5-bromodeoxyuridine extracted from the small proportion of cells which were non-viable or died at the time of transfer to 5-bromodeoxyuridine-supplemented medium.

ribonuclease treatment (37°, 2 hr.) and overnight dialysis. The density gradient centrifugation procedure⁶ was employed for the fractionation of deoxyribonucleic acid labelled with 5-bromodeoxyuridine. When centrifuged for 72 hr. at 35,000 r.p.m. in a 'Spinco' swinging-bucket rotor, the normal, deoxyribonucleic acid molecules free from 5-bromodeoxyuridine converged to a position in the caesium chloride gradient corresponding to a density of approximately 1.703 gm. cm.⁻³ (Fig. 1). This was determined either by analytical caesium chloride centrifugation⁶ or by measuring the density and deoxyribonucleic acid content (optimal density at 260 mμ) of all the fractions, 30-90 µl. each, collected by the method described by Szybalski⁷. Specific transforming activity for 3 genetic markers was determined for each fraction, employing indole, methionine, and histidine-deficient receptor strains of *B. subtilis*. The methods for preparation and treatment of recipient cells were essentially the same as described by Spizizen². As can be inferred from Fig. 1, the specific transforming activity, expressed as the number of transformant colonies per µgm. deoxyribonucleic acid (using a standard number of 10³ recipient cells per ml., under standard conditions), was practically identical for all the fractions of normal, deoxyribonucleic acid free from 5-bromodeoxyuridine.

Similar determinations were performed on 5-bromodeoxyuridine-labelled, caesium-chloride centrifuged and fractionated transforming deoxyribonucleic acid. The fact that this labelled deoxyribonucleic acid formed bands at only three density-levels, corresponding to the parental, and hypothetical

'unifilarly' ('hybrid'), and 'bifilarly' labelled molecules, is consistent with the hypothesis of semi-conservative replication of *B. subtilis* deoxyribonucleic acid, by analogy with the data of Meselson and Stahl⁶. As briefly reported earlier (indole marker)⁸, and as can be seen in Fig. 2, heavy labelling with 5-bromodeoxyuridine of the transforming deoxyribonucleic acid in one (1.742 gm. cm.⁻³ peak) or both (1.776 gm. cm.⁻³ peak) strands did not significantly affect the specific transforming activity for the three markers tested. The labelled deoxyribonucleic acid used in this experiment was highly polymerized with sedimentation constant $S_{20,10} = 44s$ (corrected for deoxyribonucleic acid concentration equal to 0), and essentially free of any denatured material, as inferred from the shape of the 'melting' profile^{9,10}.

In summary, it might be concluded that transforming *B. subtilis* deoxyribonucleic acid molecules retain their biological activity even after extensive 'unifilar' or 'bifilar' labelling with 5-bromodeoxyuridine, as assessed with three genetic markers.

Crystallization of the Complex of D-Amino-Acid Oxidase and Benzoate

WE have been investigating D-amino-acid oxidase apo-protein, flavin adenine dinucleotide and the substrate with reference to complex formation^{1,2}. In the previous communication¹, it was reported that the addition of the apo-protein to flavin adenine dinucleotide causes a shift and decrease of the absorption peak at 450 mμ of the latter. It was also found that the co-existence of benzoate, a substrate-substitute, and the apo-protein causes further marked

Fig. 1. Crystal of the complex of D-amino-acid oxidase holo-enzyme and benzoate. ($\times 1,000$)

changes in the absorption spectrum of the flavin adenine dinucleotide. Two important changes were especially noted: (1) the intensity of the absorption at 450 mμ is further decreased and that at 485 mμ is increased to form a shoulder, and (2) a new absorption peak appears at 465 mμ. These results indicate that both the apo-protein and the benzoate combine with two different binding sites of the isalloxazine nucleus of flavin adenine dinucleotide. On the other hand, the fact that benzoate competes with the substrate, D-amino-acid^{3,4}, indicates combination between benzoate and the apo-protein. Hence it may be considered that the apo-protein, flavin adenine dinucleotide and benzoate combine to form a tight complex⁵.

We have now isolated the complex of D-amino-acid oxidase apo-protein, flavin adenine dinucleotide and benzoate. Excess of both flavin adenine dinucleotide and benzoate was mixed with the apo-protein dissolved in pyrophosphate buffer (M/60, pH 8.3) at 0°. Then, ammonium sulphate to 0.2 saturation was added to this mixture, bringing the pH to 5.1. A yellow precipitate was obtained by centrifugation. This precipitate was dissolved in pyrophosphate buffer (M/60, pH 8.3) and precipitated by ammonium sulphate at pH 5.1. The precipitate was dissolved in its own volume of pyrophosphate buffer (M/60, pH 8.3), and allowed to stand at room temperature. Needle-shaped crystals then appeared (Fig. 1).

The absorption spectrum of the crystallized preparation is shown in Fig. 2, curve I. The shape of this absorption spectrum is identical with that of flavin adenine dinucleotide co-existing with both the apo-protein and benzoate¹.

The presence of benzoate in this crystal was assumed, and the benzoate was determined. The solution of the crystal was acidified with dilute hydrochloric acid, and benzoic acid was extracted with ether, from which it was re-extracted with 0.01 N aqueous potassium hydroxide. For the estimation of benzoate, its absorption at 225 mμ was measured. The presence of benzoic acid in the solution was shown by Folin's reagent after oxidation by hydrogen peroxide. The results showed that the

Fig. 2. Spectrum of the complex of D-amino-acid oxidase holoenzyme and benzoate. Curve I, spectrum of the solution of the crystal; the crystal was dissolved in 0.05 M potassium phosphate buffer, pH 6.3; curve II, spectrum of the same solution 5 min. after the addition of an excess of D-alanine. The spectra were obtained with a Hitachi recording spectrophotometer at room temperature

crystal contained equimoles of the apo-protein, flavin adenine dinucleotide and benzoate.

The enzyme activity of this crystallized sample was also examined. Complete decolorization was demonstrated by the addition of excess D-alanine, as shown in Fig. 2, curve II. With excess D-alanine, this sample showed the same turn-over as that of the apo-protein reported previously⁸.

It was also found that when an excess of D-alanine was added to the sample, and the enzyme was precipitated by ammonium sulphate, benzoate was found in the supernatant.

From these results, it may be concluded that the crystal we obtained is the complex of reconstructed D-amino-acid oxidase holoenzyme and benzoate, and that benzoate acts as a hinge to form a tight complex of the apo-protein and flavin adenine dinucleotide without any denaturation of the active core of the apo-protein, and benzoate, a substrate-substitute, can easily be exchanged by the real substrate, D-amino-acid. Hence it is considered that the apo-protein, coenzyme and the substrate combine with each other like three corners of a triangle.

In this connexion, we have compared our crystal with 'holoenzyme of D-amino-acid oxidase' obtained by Kubo *et al.*⁷ and Massey and Palmer⁸. Kubo *et al.*⁷ reported that they obtained the holoenzyme crystal without splitting off its prosthetic group. We have examined the absorption spectrum of the solution of the crystal obtained by Kubo's method and we find a shoulder at 485 mμ. This result, together with the fact that benzoate was used during the preparation procedure of their enzyme, suggested that the benzoate may still be present in the enzyme sample. Analysis showed indeed that this sample also contains equimoles of the apo-protein, flavin adenine dinucleotide and benzoate.

Recently, Massey and Palmer⁸ reported that they obtained a crystal by further purification of Kubo's sample using a calcium phosphate gel-cellulose column and that they removed iron-containing impurities from the sample. This purification was repeated in our laboratory, and it was also found that the treatment by calcium phosphate gel-cellulose chromatography could be simplified by the following treatment: the mixture of calcium phosphate gel and cellulose powder (1:30, w/w) was added to the enzyme sample prepared by the method of Kubo *et al.*⁷, and stirred at pH 7.1. Then the pH was brought to 5.1 and the mixture centrifuged at 0°. The reddish-brown precipitate was removed. Repeating this procedure twice, a clear yellow supernatant

was obtained. A crop of needle-shaped crystals was obtained from the supernatant.

The absorption spectrum of the crystallized sample obtained by the method of Massey and Palmer⁸ and that obtained by the simplified method were identical with that of our crystal synthesized from the apo-protein, flavin adenine dinucleotide and benzoate (Fig. 1, curve I).

The quantity of benzoate in this crystallized sample was also estimated, and it was found that equimoles of the apo-protein, coenzyme and benzoate were present in the sample.

From these results, it is considered that the crystal of 'D-amino-acid oxidase' obtained by Kubo *et al.* and also that by Massey and Palmer are not the enzyme itself, but a complex of D-amino-acid oxidase holoenzyme and benzoate.

The Phenazinimines: a Possible Explanation of Anomalies associated with Neutral Red

D. L. Vivian and Morris Belkin in 1956 reported¹ that they had synthesized a compound which from the 'unambiguous' method used² should be 2-amino-8-dimethylamino-3-methylphenazine:

This is the accepted structure for the colour base of neutral red, and a compound having this configuration, when converted to its hydrochloride, should show the normal neutral red behaviour of acting as a vital stain, that is, should stain living cells without killing them. As stated by Vivian and Belkin, however, the compound actually obtained, although giving an analysis agreeing with I, when converted to its hydrochloride, did not show the characteristic vital staining behaviour of neutral red. It also differed from the colour base obtained by removing the hydrogen chloride from a sample of commercial neutral red through chromatographic adsorption on basic alumina, in that it had a very different melting point, as well as in giving a brown colour with concentrated sulphuric acid, instead of the deep green colour which the commercial base forms. Still another point of difference is that the free base from the commercial neutral red fluoresces very slightly if at all in ether

solution, while the more soluble synthetic fluoresces a very strong green under ultra-violet illumination.

It was found possible by solution in sulphuric acid to convert the new base into one which did behave as the base obtained from commercial neutral red, and also gave the characteristic vital staining of cells from two varieties of *Amoeba* and from sarcoma 37 ascites tumour when it was converted to its hydrochloride, but no attempt was made in this first report to arrive at an explanation of the true nature of the new compound.

Now, however, as a result of further consideration of the problem, together with that of some experimental facts already known, but with which the authors were unacquainted at the time, I have formulated the following possible explanation:

By analogy with 1- and 2-phenazinol, which have been shown to be tautomeric, respectively, with 1(5H)-phenazinone, and 2(10H)-phenazinone³, it seems highly probable that equivalent systems exist with 1- and 2-aminophenazine:

Following the nomenclature of the corresponding keto compounds: it is suggested here that II might be called 1(5H)-phenazininimine, and III, 2(10H)-phenazininimine, as shown above.

Just as Badger, Pearce, and Pettit have stated³ that the system 1-phenazinol-1(5H)-phenazinone must exist primarily, if not entirely, in the hydroxy form, due to hydrogen bonding with the nitrogen atom in the 10-position, so, too, it is probable that the amino form predominates in the system 1-aminophenazine-2(5H)-phenazinone, even though the predominance would not be expected to be as great. For the sake of academic completeness, however, both the 1-aminophenazine and the 2-aminophenazine systems are illustrated here.

The tautomers of the unsubstituted phenazinol-phenazinone systems apparently are incapable of independent existence, as by analogy are probably those of the unsubstituted aminophenazine-phenazininimine systems also. However, appropriate substi-

tution has made it possible to isolate both forms in one system, at least, that of 1,3,4-trimethyl-2-phenazinol-1,3,4-trimethyl-2(10H)-phenazinone⁴. Hence, in view of the demonstrated fact that separable isomers of 2-aminophenazine do exist when the compound is further substituted by an amino or hydroxyl group in the 8-position¹, it seems a reasonable hypothesis that their structures are wholly analogous to those of the phenazinol-phenazinone systems. If this be true, the two forms of the colour base of neutral red must be as shown below:

Existence of a third compound, arising from the higher-temperature neutralization of the sulphuric acid solution of the non-staining form of the base, as is likewise mentioned in the paper by Vivian and Belkin¹, may possibly be due to polymerization under these conditions, but no definite conclusions can be drawn without further work.

Constraints in the Determination of Active-Centre Topography

THE inactivation of succinic semialdehyde dehydrogenase by trypsin has recently been found to be accelerated by a factor of greater than 100 when triphosphopyridine nucleotide, a substrate of the dehydrogenase, is included in the reaction mixture¹. Evidence was presented that the site at which triphosphopyridine nucleotide is effective is the same for both dehydrogenase activity and for acceleration of inactivation by trypsin. It was concluded that the binding of a pyridine nucleotide substrate to succinic semialdehyde dehydrogenase produces a configurational change in the enzyme, and, in so doing, results in the exposure of a linkage labile to trypsin. Indirect evidence of such configurational changes has been noted by others²⁻⁴ and suggests that the phenomenon may be of widespread occurrence.

These considerations lead to pertinent deductions concerning the relationship of enzyme topography and enzyme activity. Consider the above-noted case of succinic semialdehyde dehydrogenase¹. Clearly, the enzyme can exist in at least two different geometric shapes which may be designated as form A (the structure of the enzyme in the absence of triphosphopyridine nucleotide) and form B (the enzyme in the presence of triphosphopyridine nucleotide), respec-

tively. It is understood that additional forms of the enzyme are not precluded. Since the active centre of an enzyme may be deformed by interaction with the substrate, simultaneous determination of the reaction-rate and the original geometry of the enzyme molecule (form A) are not possible. It should be noted that in actual practice estimations of the dimensions of enzyme active centres are arrived at by measuring relative reaction-rates of substrates and structurally related inhibitors. In view of the foregoing argument, these data cannot logically be used to approximate the molecular configuration of the initial state of the enzyme, that is, form A.

A possible extension of this concept is that the active centre may not be deformed by each substrate in precisely the same manner, but may be shaped within limits by the particular substrate^{3,4}.

World-wide Distribution of Iodine-131 in Animal Thyroids following Announcements of Isolated Nuclear Weapons Tests in North Africa

MOST nuclear weapons tests have been associated with repeated releases of fission products within a few weeks, and the iodine-131 in animal thyroids increased progressively with succeeding tests¹. In February and April 1960, individual nuclear weapons tests were announced to have occurred in the Sahara Desert. The results on which this report is based were obtained by analysis of preserved thyroid glands sent to the University of Tennessee by volunteer correspondents.

The gamma-radioactivity of the thyroid glands was measured as described in 1956 (ref. 1) and the radioactivity was corrected to the date of slaughter of the animals.

The graphs in Fig. 1 show that iodine-131 of the animal population had reached very low levels before February 10, 1960, except for animals raised near Nashville, Tennessee. The first increases in thyroid iodine-131 content following the test of February 13, 1960, were found in sheep from Haifa, Israel, on February 21, and Portugal on February 23, 1960. On February 24, the cattle from Formosa contained one hundred times more iodine-131 than they previously had in January and February of 1960. There is a strong suggestion that pigs from Memphis, Tennessee, had increased amounts by February 24, 1960. In March 1960, there were increases in thyroid radioiodine in all the animal populations which I sampled. The highest concentrations of radioiodine were found in the thyroids of sheep from Portugal; otherwise the concentrations of radioiodine in animal thyroids reached quantitatively similar maxima in sheep from Germany, London and Nashville and in cattle from Memphis and Formosa. The sheep thyroids generally contained more radioiodine than those from cattle.

Fig. 1. Micromicrocuries of iodine-131 per gm. of thyroid corrected to date of slaughter of unselected slaughterhouse animals from January to July 1960. 788 thyroids from Memphis cattle, 302 Memphis pigs and 394 Nashville sheep were tested. 88 thyroids from the Republic of China, sent by Dr. Yu-hsi M. Wang, University of Taiwan. 35 cattle and 61 sheep thyroids from Munich, Germany, sent by Karl Schury of Max Muhlpointner A.G. Glands from 464 sheep were sent by E. F. McCleery from London. 35 cattle thyroids were sent from Japan by R. Tanaka, Ibaraki University. 111 cattle and 176 sheep glands were sent by Mr. A. Ciolini, Seattle, Washington. 247 sheep thyroids were sent by Dr. Roger Melick, of the University of Melbourne. 161 sheep thyroids were sent by Dr. J. Amaral Mendes, of the Laboratorio Nacional de Investigacao Veterinaria, Lisbon. Dr. Kurt Steinitz, of Haifa, Israel, sent sheep thyroids slaughtered in Haifa on February 21 and 24, 1960.

The relatively large concentration of thyroid iodine-131 in pigs from Memphis was unexpected.

There is a definite tendency towards biphasic iodine-131 concentration curves in Fig. 1 during the period February–April, even though it is thought that only one nuclear test was conducted during that time. This biphasic character is similar to curves obtained from Australian sheep in December of 1957 (ref. 2) and may be characteristic of iodine-131 accumulation after nuclear tests. Another explanation of two maxima between February and April would be the presence, that I cannot explain, of new iodine-131 in the atmosphere, similar to the increased iodine-131 observed in sheep at Nashville in January 1960. After April 1, 1960, in most animal populations the radioactive iodine disappeared with a half-life which was greater than eight days, probably because of the

addition of new fission products after April 1. The sheep population around Munich, Germany, and in Portugal received the most iodine-131 after the test of April 1, but the sheep in London and Nashville received the greatest amounts of iodine-131 before the April 1 nuclear test. The observations available are not sufficient to explain these differences. Cattle in Japan and sheep in Australia showed very small amounts of iodine-131 from the weapons test in North Africa. The amount of fall-out in Australia was probably reduced by the great distance of Melbourne from the latitude of origin of the fission products. Japanese cattle have usually had less iodine-131 than other populations during the past five years.

The maximum concentration of iodine-131 in the sheep at Nashville was observed in March and quantitatively it was similar to that observed 38 months previously, when the iodine-131 in sheep thyroids (in December 1956) was believed to have had its origin in northern Siberia in November 1956.

These observations show again that the monitoring of radioiodine in thyroid glands of grazing animals is a sensitive and informative method for evaluating the biological exposure of animal populations to fission products.

This investigation was supported by a research grant from the United States Atomic Energy Commission.

PHYSIOLOGY

Auto-Antibodies against Antigen derived from Colon in the Microsomes of Regional Colonic Lymph Glands in Human Ulcerative Colitis

THE sera of children with ulcerative colitis have been shown to contain a γ -globulin which reacts with an antigen prepared by phenol-water extraction of human colon. The serum factor may be termed an auto-antibody¹. This communication presents evidence that antibody against the same antigen also occurs in the regional colonic lymph glands but not in the ileal glands of the patients and that it is bound to the microsomes of the colonic glands.

About 10 gm. of regional colonic lymph glands were obtained during colectomy from each of two children (A and B) with severe ulcerative colitis. In patient B regional ileal lymph glands (5 gm.) were obtained from the mesentery at a distance of 40 cm. from the ileocecal valve. Serum from these two patients and from others was also available.

Immediately after surgery the glands were homogenized with a Potter-Elvehjem homogenizer in ice-cold 0.25 M sucrose with 0.001 M Mg^{2+} . Twice-

Table 1. HÆMAGGLUTINATION OF SHEEP RED BLOOD CELLS COATED WITH PHENOL-WATER EXTRACTED ANTIGEN FROM HUMAN COLON

Test solutions	Patient A		Patient B	
	Protein (mgm./ml.)	Titre*	Protein (mgm./ml.)	Titre*
Microsomes from colonic glands	3.75	0	4.00	0
Cell sap from colonic glands	10.50	16	18.50	64
Microsomes from ileal glands			4.50	0
Cell sap from ileal glands			16.00	0
Serum of patient		128		32
Norman human serum		0		0
Physiological saline		0		0

* The titres are the reciprocal of the highest dilutions giving macroscopically visible hæmagglutination when 1 ml. aliquots of serial dilutions of the fractions or the sera were mixed with equal volumes of a 0.5 per cent suspension of coated red cells. The antigen solution used for coating contained 100 μ gm./ml. of the lyophilized material. The two experiments (patients A and B, respectively) were made on different days, using different samples of red blood cells and different antigen solutions for coating. Controls with uncoated red blood cells were negative in all cases.

washed microsomes (sediment after centrifugation at 105,000g) and cell sap (final supernatant) were prepared following Kern *et al.*². The microsomal sediments were finally homogenized again and suspended in the sucrose medium to the original concentration. Protein was determined according to ref. 3.

In the immunological tests, sheep red blood cells were coated by the Middlebrook-Dubos method⁴ with antigen extracted from foetal colon¹. Cell sap and sera were inactivated (56° C., 20 min.) before use and absorbed with sheep red cells to remove heterophile antibodies.

Table 1 shows the results of two typical experiments. As can be seen, the hæmagglutinating activity was confined, in both patients, to the serum and cell sap of the colonic lymph glands. The cell sap of the ileal lymph glands was inactive. No hæmagglutination was obtained with any of the three microsomal fractions. However, there is some evidence that antibody bound to microsomes is non-hæmagglutinating⁵. On the other hand, Kern *et al.*² have demonstrated antibody in microsomes of lymph nodes from immunized animals by its antigen-combining capacity. Therefore, in a second series of experiments, the antigen-binding capacity of serum and of the various fractions from the colonic lymph

† 1 ml. aliquots of antigen in saline (150 μ gm./ml.) were incubated for 4 hr. at 20° C., with 2 ml. of either one of the samples indicated in columns 1-5. Columns 4 and 5: controls. No precipitate appeared in the incubation mixtures.

‡ 1 ml. of a red blood cell suspension was added to each of the incubation mixtures.

§ After washing, hæmagglutination was performed with a known hæmagglutinating serum from another patient. Titres are the reciprocals of the highest dilution of antiserum giving macroscopically visible hæmagglutination with equal volumes of a 0.5 per cent suspension of coated red cells.

Fig. 1. Hemagglutination of sheep red blood cells, coated with antigen incubated with various preparations from patient B. 1 ml. aliquots of the antigen (150 μ g./ml.) were incubated with 2 ml. of either undiluted microsomes or cell sap (see Table 1 for analytical data), serum from the patient, or normal serum. In addition, aliquots of the antigen were also incubated with 2 ml. samples of microsomes, diluted with their homologous cell sap in three different proportions, or with similar mixtures of patient serum and normal serum. For details of incubation, see Table 2. The hemagglutinations were performed with a known positive serum from another patient. Abscissa, proportions (per cent) in which the various fractions (A and B) were mixed before they were added to the antigen for incubation. Ordinate, reciprocal of highest dilution of antiserum giving macroscopically visible hemagglutination. In the control where antigen had been diluted with 2 ml. of physiological saline, the hemagglutination end-point was 512.

●, Colonic glands; A, cell sap; B, microsomes. ○, Ileal glands; A, cell sap; B, microsomes. △, Serum; A, normal serum; B, antiserum

glands was measured. The procedure is outlined in Table 2, which shows the results of a typical experiment with the specimens from patient A. It will be seen that incubation of the antigen with normal human serum did not abolish its ability to sensitize the red cells. In contrast, incubation of the antigen with microsomes, cell sap or serum of the patient prevented hemagglutination completely. Similar results were obtained with the specimens from the second patient. Fig 1 shows the typical results of an experiment made with all the samples obtained from patient B. The figure reveals that the inhibiting capacity of the cell sap from the colonic glands was appreciably lower than that of an equally diluted sample of the microsomes. The inhibitory capacity of undiluted serum from this patient was also lower than that of the colonic microsomes. However, since the chemical nature of the antibodies is unknown, no conclusions can be drawn regarding their concentration in the different preparations. Microsomes and cell sap from the ileal glands, as well as normal human serum, were inactive.

The mechanism of hemagglutination inhibition by immune microsomes is unknown. It could be assumed that both antibody-active particles and antigen are bound to the red cells. In this case the molecular structures responsible for adsorption of the antigen to the red cells would be different from the structures combining with antibody. This has actually been shown for the α -haemosensitizin of *Mycobacterium tuberculosis*⁶; this substance can be adsorbed directly to the red blood cells by the Middle-

brook-Dubos procedure⁴. Although the immunological activity resides in the polysaccharides constituting the bulk of the material, a small lipid fraction seems to be necessary for sensitization⁶.

The finding of antibodies in colonic gland microsomes is in agreement with that of other workers who found antibodies in splenic or lymphatic microsomes of immunized animals^{3,5,7}. In contrast, microsomes (and cell sap) of more distant lymph glands were devoid of antibody activity. This would appear to rule out the possibility that the antibodies in the regional colonic glands were adsorbed serum antibodies. In this connexion, it should be mentioned that Kern *et al.*⁸ could not find any adsorption of antibodies when antiserum was added to isolated microsomal fractions from non-immunized animals. Rather, then, the presence of antibodies in our samples would reflect a synthetic activity occurring in the microsomes of certain cells in the regional colonic glands. There is considerable evidence that proteins which are secreted are synthesized by the ribonucleoprotein particles, constituting a part of the microsomal fraction^{9,10}. Before being released into the cell sap or the medium, the products of the synthetic activities of the particles often remain temporarily attached to the membranous elements which also are obtained in the microsomal fraction upon ultracentrifugation⁴. In order to study the mode of intracellular binding, attempts were made to solubilize antibodies from the microsomes by means of phospholipases and various detergents which are known to liberate proteins from the membranous parts of the microsomal fraction^{9,10,11}. In a number of preliminary experiments, positive precipitin reactions were obtained in agar diffusion tests, using extracts of microsomes treated with phospholipase A from bee venom. Preliminary attempts to liberate precipitating or hemagglutinating antibodies from isolated ribonucleoprotein particles by increasing the pH, treatment with chelating agents or with ribonuclease^{5,7} have been unsuccessful.

In the homograft reaction, immunologically competent cells have been shown to be localized in the regional lymph nodes¹². If immune reactions play any part in the pathogenesis of ulcerative colitis, it is likely that the lesions are the expression of a hypersensitive state, mediated by cell-bound antibodies of the same type as those participating in the homograft reaction, or in delayed hypersensitivity¹³. It is therefore of interest that, in the present case, isolated subcellular structures of regional colonic lymph glands exhibit an antigen-binding activity without foregoing extraction. Thus tissue lesions might be initiated by the binding of antigen on cells of the colon to antibody-bearing membranes of the immunologically competent cells. It is possible that in the latter cells antibody-active protein is transported from its site of formation, perhaps on the ribonucleoprotein particles, to the surface of the cell. The cell membrane is supposed to be chemically and morphologically related to the endoplasmic reticulum and its fragments will probably appear in the microsomal fraction¹⁴. A surface antibody of this nature could be of some importance in delayed hypersensitivity¹⁵.

Diurnal Changes in the Topographical Distribution of Glycogen in the Brain of *Iguana iguana*

RECENTLY I investigated the topographical distribution of glycogen in the brain of *Iguana iguana* in relation to the environmental temperature, and in animals with glycogen-accumulation disease¹. It appeared that a decrease in environmental temperature results sometimes in a decrease in concentration of the glycogen in the brain tissue, and in some cases an increase, for in animals with heptomegalia glycogenice the glycogen concentration in the tissue of the cortex cerebri, the diencephalon, the mesencephalon, the cerebellum and the medulla oblongata increases significantly.

In continuation of these experiments the diurnal changes in the brain glycogen of *Iguana* were investigated. For this purpose the concentration of the brain glycogen was determined in 60 males and 60 females at 6-hr. intervals in the five topographical regions of the brain mentioned. The environmental temperature at which the animals were kept was $36.8 \pm 0.3^\circ \text{C}$. For the glycogen determination I used Kerr's method², the reduction compounds being determined by Nelson's method³ (see also in this connexion the paper of Jakoubek and Svorad⁴). The glycogen values are given in mgm./100 gm. fresh brain tissue in Table 1. For the determination of each value 15 animals were used.

As can be seen from Table 1, there are no significant periodic changes in the cortex cerebri, the mesencephalon, the cerebellum and the medulla oblongata. However, in the diencephalon a significant difference in the glycogen concentration can be seen.

Thus, the changes in concentration of the brain glycogen not only run parallel to several altered states of behaviour in the individual^{5,7}, but are also related to the autonomic functions, which are regulated at the highest level.

These results correspond with those of Svorad⁵ obtained in the rat.

Muscular Dystrophy in the Siamese Fighting Fish as an Aberration of the Connective Tissue

RECENTLY I carried out a histochemical study of the ability of connective tissue in normal muscles and atrophied muscles of *Iguana iguana* to dephosphorylate various high-energy phosphates derived from adenosine monophosphate and some other compounds¹.

In continuation of this work I carried out a corresponding investigation in a fish, namely, the Siamese fighting fish *Betta splendens* Regan, belonging

Table 1. DIURNAL CHANGES IN GLYCOGEN CONCENTRATION IN THE BRAIN OF *Iguana iguana*. THE GLYCOGEN VALUES ARE GIVEN IN MG./100 GM. FRESH BRAIN TISSUE. FOR THE DETERMINATION OF EACH VALUE 15 ANIMALS WERE USED. M, MALE; F, FEMALE

to the family Anabantidae. In this species a distinct senile period occurs, in which the animals are seen to move slowly near the surface of the water. For this investigation very old specimens were used, in which a progressive muscular dystrophy had occurred.

For the determination of the 5-nucleotidase activity of the material, the histochemical methods of Beckett and Bourne² were used.

Since adenosine monophosphate is dephosphorylated by 5-nucleotidase, the ability of the connective tissue to bring about dephosphorylation of various high-energy phosphates derived from adenosine monophosphate in the normal and atrophied muscles of *Betta* was investigated. In addition, some other phosphate compounds of a certain physiological importance and some other esters were investigated. These substances were adenosine diphosphate, adenosine triphosphate, creatine phosphate, acetyl phosphate, cytidine, inosine, guanosine, pyridoxal phosphate, thiamine pyrophosphate, riboflavin-5-phosphate, diphosphopyridine nucleotide, triphosphopyridine nucleotide, phosphoglyceraldehyde, hexose-diphosphate, fructose-1- and 6-phosphates and glucose-1- and glucose-6-phosphates. The histochemical reactions of all these compounds were compared with that of β -glycerophosphate.

In the 81 cases of muscular dystrophy in *Betta*, with the exception of creatine phosphate, dephosphorylation of the above-mentioned high-energy phosphate compounds by the elements of the connective tissue and by a number of the muscle fibres was observed. However, the intermediate glycolytic compounds showed no hydrolysis.

By the dephosphorylation experiments in fourteen of the 81 cases I was able to establish a dephosphorylation of thiamine pyrophosphate. The co-enzymes pyridoxal phosphate and riboflavin-5-phosphate could not be demonstrated to be affected.

In all cases of progressive muscular dystrophy in *Betta* the elements of the connective tissue were found to dephosphorylate the diphosphopyridine nucleotide and the triphosphopyridine nucleotide. Just as in the muscular dystrophy of man³ and of *Iguana*⁴, in the case of the diphosphopyridine nucleotide a stronger dephosphorylation was observed than in that of the triphosphopyridine nucleotide.

Summarizing, we may conclude that in the elements of the connective tissue surrounding the muscle fibres, enzymes destructive of compounds vital to muscular metabolic processes have been identified with certainty. These enzymes must no doubt play a certain part in the genesis of the progressive muscular dystrophy.

Just as is the case in man³ and in *Iguana*⁴, the pathological changes in the muscles of *Betta* in progressive muscular dystrophy consist of an increase in number of the sarcolemmal nuclei, an atrophy of the muscle fibres, a great diversity of the size of the muscle fibres, a proliferation of the elements of the connective tissue and storage of varying amounts of fat. The sarcolemmal nuclei may assume the form of chains localized centrally in the muscle fibres. Between these changes and those in progressive muscular dystrophy in man there is a good correspondence.

Adams, Denny-Brown and Pearson⁴ arrived at the conclusion that phagocytosis of degenerating muscle fibres is rare. Bourne and Golarz², however, found evidence in a number of cases for what appears to be

an invasion and a destruction of muscle fibres by the neighbouring connective tissue.

Bourne and Golarz², who by their study of ten cases of progressive muscular dystrophy in man obtained corresponding results, have given three possible interpretations, namely: (1) The primary defect may still be in the muscle-fibre membrane. In this connexion, the diffusion of the phosphate esters from the muscle fibres into the neighbouring medium may result in the adaptive synthesis of certain enzymes to hydrolyse them in the elements of the connective tissue. (2) The synthesis of the metabolically very important phosphate compounds occurs in the muscle fibres, but nevertheless there may be some leakage in the normal metabolism, much in the same way as the vitamin A leaks away from the retina in the retinene-cycle. The replacement of this leakage by transport from the lymphatic and the vascular system, if there is inadequate synthesis by the muscle fibres themselves, would be prevented by the connective tissue elements, which contain the appropriate phosphorolytic enzymes. (3) The production of the hydrolytic enzymes by the elements of the connective tissue may lead to diffusion of these enzymes into, as well as adsorption on to, the membrane of the muscle fibres, and possibly penetration of this membrane, resulting in a complete blockage of the normal metabolic processes of these fibres.

Comparing these possible interpretations, Bourne and Golarz² came to the conclusion that the fundamental defect in progressive muscular dystrophy in man may be in the elements of the connective tissue supporting the muscle fibres, and not in these fibres themselves (possibility 1).

On the other hand, possibility 2 is not sufficiently in agreement with current views on the metabolic processes in the muscle fibre. Possibility 3 is not so probable either, because the penetration of the sarcolemma by the hydrolytic enzymes has still to be established. It is not improbable that the accumulation of such a range of phosphatases at this site might break down its structural integrity as well as its selective permeability.

My results obtained in the muscular dystrophy of *Betta* and of *Iguana*⁴ point in exactly the same direction, and may therefore be an argument for the concept that an aberration of the neighbouring connective tissue is the primary cause of the muscular dystrophy in fishes as well as reptiles.

Initiation of Mammary Secretion in Rats by Electrical Stimulation of Nervous System

DURING recent years the interaction of neural and endocrine factors in the initiation of mammary secretion in different species of animals is being increasingly recognized, and it has been shown that electrical stimulation of the uterine cervix of oestrogen-primed virgin female rats can initiate mammary

secretion¹. In the present experiments, attempts were made to determine whether electrical stimulation of other areas would similarly result in mammary secretion.

Virgin female rats were injected subcutaneously daily with 10 µgm. oestradiol for 10 days to develop their mammary glands. For the following 5 days, groups of rats were electrically stimulated for 30 sec. twice daily in the regions of the head, lumbar vertebrae, nasal mucosa and nipples. Control rats were injected twice daily with saline for 5 days. On the sixteenth day, the rats were killed, and the right inguinal mammary glands were removed for histological preparations. The mammary glands of the controls regressed to a bare duct system, whereas almost all the electrically stimulated rats showed maintenance of the mammary lobule-alveolar system and initiation of lactation. These results suggest that electrical stimulation of the central nervous system induces release of prolactin and adrenocorticotrophic hormone from the anterior pituitary, since both hormones are required to induce mammary secretion in the oestrogen-primed rats.

HÆMATOLOGY

Anti-i : a New Cold Antibody

In 1956 Wiener and his colleagues¹ described an antibody occurring in a case of cold antibody hæmolytic anaemia which they called anti-I. The I antigen has an almost universal distribution, but five examples of i cells were found in testing 22,000 donors. It was considered that the Ii phenotypes arose by the action of two allelomorphous genes I and i, individuals of the phenotype i being ii.

More recently, Jenkins *et al.*² have described an English donor whose cells are i and whose serum contains a naturally occurring anti-I that is not auto. Using these cells, the antibodies in a number of other cases of cold antibody hæmolytic anaemia were also found to have I specificity. At the same time Tippet *et al.*³ have reported a number of blood samples that are extremely weak in I although not as weak as the i donor of Jenkins *et al.* The serum of these people also contains anti-I that is not auto.

The results of the above workers show clearly that i cells also contain some I, but an enormous gulf separates them from the I of normal adults. Cord-blood cells were also found to be extremely weak in I.

Recently, we encountered a remarkable antibody that appears to clarify the Ii relationship in human red cells. This antibody was found in the serum of a patient not yet diagnosed but probably suffering from a reticulosis.

The serum of this patient weakly agglutinated his own and 500 normal adult red cell samples at low temperature (average titre at 12° C. about 1 in 10). Tests with three examples of i cells and five examples of the slightly stronger variant described by Tippet *et al.* all gave strongly positive results with titres ranging from 1 in 32,000 up to 1 in 250,000, the three i

samples all giving maximum titres. More than 40 cord blood samples were tested and all gave strong reactions similar to adult cells of the i phenotype.

Repeated absorptions of the serum with various cells showed that a single antibody was present reacting powerfully with i and cord cells and weakly with adult I cells. Clearly this antibody has anti-i specificity. Electrophoretic studies have shown that the antibody is present in the β-globulin fraction of the serum.

Tests on a number of infants of various ages show that within 18 months of birth the i reaction becomes steadily weaker while the I reaction becomes stronger until the normal adult relationship of strong I and weak i is established. It appears that all normal adult and infant samples have some I and some i, and cells that are strong in I are weak in i and vice versa.

It is clear that the abnormality found in the cells of the rare adults of the i phenotype is not that they are i, for everyone is probably i for a few weeks of life, but that the I has failed to develop. This type of reaction surely cannot reflect the action of I and i as allelomorphous genes. We think that the abnormality found in these i adults is caused by the absence of a genetically controlled factor that is essential for the proper development of I.

Our results have shown that the anti-i serum is able to place people very precisely on the I scale in an indirect way by measuring the amount of i that they possess. In view of this the following terminology in the I group system is suggested:

Details of these results will be submitted for publication elsewhere.

Ageing of Haemoglobin

THE problem of ageing of protein molecules has been considered by several authors. Kunkel¹ in man, Ranney² in the rabbit, have attempted to demonstrate the ageing of haemoglobin, taking advantage of the metabolic heterogeneity of haemoglobins described by us in 1950³. They observe, indeed, during the life of the red cells, an equalization of the specific activities of haemoglobin fractions which were unequal initially. These authors were using iron-59, and it is known that iron is re-utilized after the death of the red cells: this prevents observation of an eventual crossing of the specific activity curves of different fractions in the course of the ageing of the

red cells. Therefore they cannot decide between the two following hypotheses: (1) there are metabolic exchanges between the fractions, contrary to the theory of the metabolic inertness of haemoglobin; (2) there is ageing of part of the haemoglobin, which during this process changes its electric charge and becomes concentrated in one of the fractions.

In an attempt to overcome this difficulty, we used valine labelled with carbon-14, which we injected intraperitoneally into rabbits weighing 2-3 kgm. at a dosage of 8 μ C/kgm. Blood was removed at various intervals from 1 to 80 days after injection.

Haemoglobin was prepared as the carbon monoxy derivative and purified by salting out⁴. Checks of purity were made by starch-gel electrophoresis in phosphate buffer pH 6.5, μ 0.033 (ref. 5). The haemoglobin samples were then submitted to electrophoresis on starch blocks in veronal buffer pH 8.6, 0.05 M for 16 hr. under 5 V./cm.

Under such conditions we obtained two fractions: a major one (R_1) and a minor one which migrated more towards the anode (R_2). No fraction corresponding to haemoglobin A_2 was observed in the rabbit. The respective amounts of main and minor fractions were 90 and 10 per cent. These percentages were relatively constant from one rabbit to the other and did not vary for the same rabbit.

Each fraction was eluted with water and centrifuged at 15,000g for 1 hr. The eluates were precipitated with trichloroacetic acid, washed several times with water, acetone and ether, and dried *in vacuo*. The powders so obtained were prepared as pellets (compression, 5,000 lb. per sq. in.). Their activity was then determined with a flow counter and the specific activity computed after correction for thickness.

Fig. 1. Variations of specific activity of the two fractions of rabbit haemoglobin at different times

Fig. 1 shows how the specific activity of the two fractions varies; the results from one rabbit only was used for this graph. The experiment was repeated on six different rabbits, and results are given in Table 1.

The specific activity of R_1 increases up to a plateau, which is reached after 5 days and is maintained for about 40 days, after which it declines. That of R_2 is initially lower; it reaches and passes that of R_1 near the thirty-fifth day and then begins to decrease without showing a plateau, but it remains higher than R_1 .

These observations confirm once more the metabolic heterogeneity of rabbit haemoglobin. On the other hand, the inversion of the ratio of the specific activity of the haemoglobin fractions according to time is a completely new fact. It involves a progressive enrichment in ¹⁴C valine of the R_2 fraction with time.

Table 1. RATIO OF SPECIFIC ACTIVITY, R_2/R_1

	52	1.28
	59	1.18

This fact cannot be explained only by metabolic exchanges between the two haemoglobin fractions, which could at most give rise to an equalization of the specific activities. The most likely explanation is that, during the ageing of the red cell, part of the haemoglobin itself undergoes modification. It becomes more electronegative, which changes its motility. So after the fortieth day the anodic fraction contains a high proportion of the labelled haemoglobin. Its specific activity becomes greater than that of the main cathodic fraction, the radioactivity of which has been diluted by a large amount of newly synthesized, and therefore non-labelled, haemoglobin. These modifications must be distinguished from those observed on blood aged *in vitro*⁶, but their nature may be the same. Electrophoretic modifications of haemoglobin have been described⁷ in red cells aged *in vivo*; but these modifications may be due to difference in the molecular environment in the red cell with ageing. Our observations lead to the assumption of a change of haemoglobin configuration, involving exteriorization of negative polar groups or, on the other hand, dissimulation of positive polar groups.

PATHOLOGY

An Effect of Early Dilution on the Establishment of Lysogeny in *Salmonella typhimurium*

It is known that the frequency of lysogenic response in a culture of *Salmonella typhimurium* strain LT2, infected with the temperate bacteriophage P22, can be influenced by the ratio of phage to bacterium (multiplicity of infection)¹⁻³, and by modifying the metabolism of the infected cells soon after infection, for example, by the addition of chloramphenicol⁴. With a high multiplicity of infection a high frequency of lysogenic response is obtained. Using a low multiplicity of infection a low lysogenic response results. If these infected cells are exposed to chloramphenicol (25 $\mu\text{gm./ml.}$) 5 min. after infection and the chloramphenicol removed by dilution 15 min. later, then practically every cell infected becomes lysogenic.

We have been examining the effect of lower concentrations of chloramphenicol in contact with cells infected with a low multiplicity of infection (2.8) for a shorter period of time. Fig. 1 shows that a concentration of 5 $\mu\text{gm./ml.}$ in contact with the cells for 7 min. is sufficient to reverse the 'decision' of the majority of the cells to lyse. What is more interesting is that the infected control culture shows a high frequency of survivors when sampled and diluted into buffer 5 min. after infection. This high frequency of survivors decreases with time until it reaches a minimum at 12 min. In all our previous experiments the control value for lysogenic response was measured at the end of the experiment and thus gave this minimum value.

In view of these results, measurements were made of the frequency of lysogenic and lytic responses of a similarly infected culture when samples were removed and diluted into buffer at room temperature during the first 15 min. after infection. The results are shown in Fig. 2. There is an evolution of the lysogenic response during this period rising to a maximum 6 min. after infection, decreasing to a minimum at 12 min. The lytic response complements the lysogenic response. These results were later found to be true, even when dilutions were made into broth or buffer at room temperature (26.5°C.) or 37°C.

Under the conditions of the experiments above, 80 per cent of the cells would have been infected with at least one phage particle by 2 min. At 6 min., 95

Fig. 2. Effect of dilution on lysogenic and lytic responses in LT2 cells infected with phage P22

per cent would be infected. This may account for the rise in lysogenic response between 2 and 6 min. after infection.

Chloramphenicol is said to reverse the 'decision' of a cell to lyse by virtue of its ability to inhibit protein synthesis⁴. The results reported in this communication indicate that dilution into fresh medium is equally effective if carried out before the 'decision' period is reached. This 'decision' period was shown by Lwoff to be 6-10 min. after infection in *S. typhimurium* infected with an $\Delta 1$ phage³. The importance of dilution in a lytic phage system has been reported by Lanni⁵, who showed that in the *T5-E. coli F* system dilution of high bacterial concentrations is necessary to stabilize the phage-host complex.

It would be interesting to know whether the effect of early dilution reported here has been found in other lysogenic systems or is restricted to *S. typhimurium*.

A Filterable Haemolysin from *Escherichia coli*

SOME strains of *Escherichia coli* are haemolytic when grown on blood-agar, and attempts made to demonstrate a soluble haemolysin in culture filtrates are usually unsuccessful. We have been able to obtain haemolytic filtrates with four such strains when grown in a culture medium prepared as follows.

A pound of lean beef is cut into small pieces and boiled in 500 ml. of N/20 aqueous sodium hydroxide. After simmering for 15 min. it is strained through a muslin cloth, and excess fluid removed. The meat is dried by pressing between filter paper and placed in a flask to which 500 ml. of infusion broth is added; the pH is adjusted to 7.6. The medium is sterilized by steaming for 24 hr. and autoclaving for 20 min. at 120°C.

Three of the strains used (0138:K81B, 0139:K82B, and 0141:K85B) were recovered from diseased

pigs¹ and the fourth (RVC58—the antigens of which are not yet determined) from diseased calves². The cultures were incubated at 37° C. for 2, 4, 6, 8, 10, 12, 18, 24, 48 and 96 hr., and filtered through 'Ford SD Sterimats' at a negative pressure of about 150 mm. of mercury. The filtrates were collected and diluted with physiological saline; they were tested against 1 per cent (final concentration) washed rabbit red cells at 37° C. Examinations were made at half-hourly intervals.

Hæmolytic activity occurred with filtrates from cultures 4–24 hr. old, the maximum activity being with cultures of 6–10 hr. The titre rarely exceeded 1:32, and no filtrate prepared from cultures grown for 48 or 96 hr. was hæmolytic. There was little variation in the pH of these filtrates (about 7.4–7.8) and all were sterile. The first portion of the fractions passing the filter was always non-hæmolytic, due probably to some absorption by the filter pad.

The hæmolysin is thermo-labile. Filtrates from 6-hr. cultures lost about half their activity when stored at 4° C. for six days, and when left overnight on the bench. Activity was reduced after 18 hr. at 37° C., while it was destroyed after 15 min. at 56° C.

Cultures were incubated in atmospheres of carbon dioxide and of hydrogen, and filtrates from these were also hæmolytic but less active. There was no evidence of a hæmolysin in filtrates from cultures grown in 1 per cent peptone water, infusion broth, 2 per cent, 6 per cent and 10 per cent serum broth.

The hæmolytic activity could be removed by treatment of the filtrate with 30 per cent aqueous ammonium sulphate. The precipitate, when redissolved, dialysed and made isotonic, was less active than the original filtrate and this decrease may be associated with the labile nature of the hæmolysin. Similar precipitates prepared from uninoculated media and a filtrate from a 6-hr. culture of a non-hæmolytic strain were non-hæmolytic.

According to Kuniicki-Goldfinger *et al.*³, hæmolysis induced by strains of *E. coli* is due to the products of autolysis. Our findings are not in accord with this, since hæmolytic activity appears to be confined to young cultures. After 10 hr. incubation this activity declines.

Development of a Leukæmia resistant to Cyclophosphamide ('Cytoxan')

THE alkylating agent, N,N-bis-(β -chloroethyl)-N',O-propylenephosphoric acid ester diamide¹ (B-518, cyclophosphamide, 'Endoxan', 'Cytoxan'), has been markedly effective in suppressing the growth of a variety of transplanted tumours in rats^{2,3} and mice³. The mechanism of activation of this agent has not been determined. It is known that the drug is not

cytotoxic *in vitro*, but is activated *in vivo*⁴. Nicotinamide has been reported to prevent the toxic and antitumour effects of 'Cytoxan'. However, the relationship of nicotinamide or diphosphopyridine nucleotide to either the activation or the action of this alkylating agent is unknown. Resistant tumours have proved valuable for the study of the mechanism of action of chemotherapeutic compounds. Sublines resistant to alkylating agents and derived from previously sensitive tumours are uncommon and have not been investigated extensively. It was thought that if a tumour resistant to 'Cytoxan' could be developed, it might provide a useful model for the study of the action of this alkylating agent.

The L-1210 leukaemia was selected for study because it was sensitive to 'Cytoxan', it could be carried in the ascites form, and it has been employed by others in studies of resistance to various anti-tumour agents. It has been reported that the effectiveness of 'Cytoxan' in increasing the median survival of mice with advanced L-1210 leukaemia was markedly enhanced by a schedule of once-weekly drug administration compared to more frequent treatment⁵. This finding suggested that the isolation of a resistant variant might be facilitated by the use of large single doses of 'Cytoxan'.

Sensitive L-1210 leukaemia was originally obtained from Dr. Lloyd Law. Four groups of CDBA mice were given intraperitoneal injections of 1–5 million leukæmic cells. Three groups of 7 mice each were treated 24 hr. later with a single intraperitoneal injection of 'Cytoxan' of 150, 180, or 200 mgm./kgm. An untreated group served as a survival control. The first mouse to develop extensive ascites in the 200 mgm./kgm. treatment group was considered most likely to harbour resistant leukæmic cells. Ascites was transferred from this animal into mice for the succeeding experiment. These animals were similarly grouped and treated. This procedure was repeated serially. The median survival for untreated mice was 7–10 days. The median survivals of mice treated with 200 mgm./kgm. exceeded those of untreated mice by 88–143 per cent. Resistance was recognized in the seventh transfer generation by a decrease in median survival of treated mice to 30 per cent beyond controls. This resistant tumour was carried in the absence of drug for 12 generations, and maintained its resistance, as shown in Fig. 1. The percentage increase in median survival beyond controls for the

Fig. 1. A group of 7 mice in each transfer generation received 'Cytoxan' intraperitoneally, 200 mgm./kgm., one day after tumour implantation. The percentage increase in median survival beyond controls is shown. CDBA male mice were used.

200 mgm./kgm. group is plotted for each transfer generation. Grossly and microscopically, the characteristics of this resistant variant, designated *L-1210/Cy-R*, and the parent leukemia are similar, as are the courses of the disease produced by each.

Resistance was also demonstrated by the following experiments. A single intraperitoneal injection of 'Cytoxan' of 250 mgm./kgm. was given to mice 1 hr. after subcutaneous implantation of 10^5 tumour cells of the sensitive leukemia. The drug prevented these cells from becoming established, and treated mice survived. Mice similarly treated after implantation with *L-1210/Cy-R* tumour cells, however, died of leukemia. Fig. 2 shows the effects of repeated weekly intraperitoneal treatment on the survival of mice bearing 5-day implants of the sensitive and resistant leukemias. A 275 per cent increase in survival beyond controls was obtained with mice bearing the sensitive leukemia, compared with only 30 per cent for those with the resistant subline.

Fig. 2. The total bar measured from the abscissa represents the percentage increase in median survival beyond controls for 10 mice with the sensitive leukemia (stippled areas), and for 10 mice with the resistant leukemia (hatched areas). Fifteen untreated controls were used for each leukemia. *CDBA* male mice were used. Intraperitoneal implant. Treatment: intraperitoneal weekly from the fifth day

L-1210/Cy-R is now in the forty-second transfer generation in the absence of drug exposure and has remained resistant. Preliminary experiments indicate that *L-1210/Cy-R* is sensitive to treatment with the antimetabolites, 6-mercaptopurine and 'Methotrexate', but cross-resistant to the alkylating agents uracil mustard, triethylene melamine, and triethylene thiophosphoramide.

RADIOBIOLOGY

Localization of Radioactivity in Tumours of Mice injected intravenously with Killed, Radioiodinated *Brucella abortus*

WORKERS studying the phagocytic activity of tumour cells seem to prefer *in vitro* systems^{1,2}. Little work appears to have been done on the ability of tumour cells to take up colloidal or particulate substances *in vivo*. Because of the possible practical importance of the subject, it was decided to study the reticulo-endothelial activity of mouse tumours. Acetone-killed, radioiodinated *Brucella abortus* (¹³¹Ibr) were chosen as the test particle, since previous work³ had shown that these bacteria are a very sensitive indicator of phagocytic activity.

Mice bearing 14-16 day old Krebs's carcinoma or 8-12 day old sarcoma-37 were used. The carcinoma was implanted into the femoral muscles of the left hind leg. The sarcoma was implanted under the skin in the region of the dorsal or lumbar vertebrae. Transplantation was performed with either trocar or syringe. In the latter case, 0.1-0.5 ml. of a dense suspension of tumour cells in phosphate buffer saline, pH 7.2, were injected. Details on preparation of bacteria, iodination and counting techniques, etc., have already been described⁴.

Groups of 5-6 mice bearing sarcoma-37, as well as untreated controls, were given intravenously (into the tail vein) 0.1 mgm. labelled *Brucella* in 0.2 ml. saline. The mice were killed after 1 hr. and the organs removed for radioactivity determinations. Blood samples were obtained by bleeding the mice from the cut neck blood vessels, while under ether anaesthesia. The blood was collected in tubes containing citrate or heparin as anticoagulants. In several experiments, the radioactivity in tumours of mice injected with ¹³¹Ibr was compared with that in tumours of mice injected with radioactive iodide. In these experiments the procedure was somewhat modified: immediately before injecting the labelled material, 5 mgm. sodium iodide were administered intra-abdominally to all mice. An additional 0.8 mgm. sodium iodide was included in the intravenous inoculum. The mice were killed 5 hr. after injection. This procedure was adopted in order to reduce the uptake of labelled iodide by the tumours.

The results are summarized in Table 1; they show that in both types of experiments a significant amount of radioactivity was found in the tumours. The distribution of the label injected as iodide was completely different from that of the label injected as iodinated bacteria.

The amount of radioactivity in Krebs's carcinoma was smaller than in sarcoma. At 1 hr. after inoculation, carcinoma-bearing legs contained about 3 per cent of the injected radioactivity, as compared to 1 per cent in the normal leg.

The radioactivity in the tumours was, in general, proportional to the weight of the tissue, although this relationship did not always hold for the individual animals. Approximately 2.4 per cent of the injected radioactivity could be found in 1 gm. of tumour at 1 hr. after inoculation.

These experiments, while demonstrating the localization of radioactivity in the neoplasms, did not provide any clues as to the mechanism involved. Attempts to detect intracellular *Brucella* in tumour

Exp. No.	Description of mice	Material injected	Radioactivity in organs				Remarks
			Tumour	Spleen	Liver	Blood (1 ml.)	
1	Normal	Iodine-131 <i>Brucella</i>	—	9.7	23.9	9.5	Organs removed 1 hr. after injection of label
2	Tumour-bearing*	Iodine-131 <i>Brucella</i>	6.1	6.1	27.7	6.9	Organs removed 5 hr. after injection of label
	Tumour-bearing	Iodine-131 as iodide	1.1	0.06	0.5	1.0	
	Tumour-bearing	Iodine-131 <i>Brucella</i>	3.1	9.7	21.0	1.3	

* This group contained six animals. All others contained five animals. The radioactivity bound to *Brucella* was 96,000 c.p.m. That injected as iodide was 121,000 c.p.m.

smears stained with May-Grünwald-Giemsa were inconclusive, apparently because of the small size of this organism. When, however, a dense suspension of heat-killed group A *Streptococci* were injected, unmistakable proof of phagocytosis by both neoplastic and stroma cells was obtained (Fig. 1). It should be added that much less radioactivity was localized in the tumour with labelled *Streptococci* than that with labelled *Brucella*.

It appears, therefore, that phagocytosis is at least one of the mechanisms leading to concentration of radioactivity in the tumour tissue. It will be interesting to see whether these results can be reproduced in man, since they might form the basis

of an additional diagnostic tool for the detection of cancer. Full details of this work will be published elsewhere.

I am grateful to Prof. J. Gross, of the Department of Experimental Medicine and Cancer Research, for discussions and suggestions during the course of this work, to Mr. G. Rasooly and Miss N. Grünwald for technical assistance, and to Dr. M. Pikovski for the supply of tumours.

Rate of Formation of Atropine in *Atropa belladonna* Plants

We have studied the biogenesis of atropine-¹⁴C in *Atropa belladonna* plants by a method which we believe to be novel in this field, but which is comparable with that applied so successfully by Calvin¹ to the elucidation of the path of carbon in photosynthesis.

A number of complete plants 2-3 months old were allowed to assimilate a single dose of carbon-14 dioxide by photosynthesis in the leaves, and were then left to continue growth under normal greenhouse conditions. At various intervals plants were killed and extracted to determine the soluble and insoluble activity remaining in the shoots and roots, and the activity in the form of atropine.

In a typical experiment, a 2-3 month old *Atropa belladonna* plant was placed in a photosynthesis chamber and fed with carbon-14 dioxide (1 mc.). It was found that more than 90 per cent of the activity was taken up by the plant during 4 hr. photosynthesis. The plant was removed from the photosynthesis chamber and grown under hydroponic conditions with the roots immersed in nutrient solution², in a greenhouse. After a suitable time of 'active' growth, the shoots and roots separately were continuously extracted for three days with boiling 80 per cent aqueous ethanol (about 250 ml.) and the activity of the extracts measured. Most of the solvent was removed under reduced pressure, and 0.2 N sulphuric acid (200 ml.) added. This acid solution was extracted with chloroform/ether (20:80) until the extracts were colourless, and after basifying the aqueous solution with ammonia, the alkaloids were extracted with the same solvent mixture. The alkaloid extract was dried with sodium sulphate, the solvents removed

under reduced pressure, and the alkaloids purified by chromatography on paper in butanol/water/acetic acid³. The atropine was washed from the paper, and carrier atropine (100 mgm.) was added and then converted into the picrate, which was crystallized several times from hot water and had melting point 176° C. Dilution analysis of the atropine-¹⁴C picrate indicated a radiochemical purity greater than 98 per cent.

The picrate was burnt in a stream of dry oxygen and the carbon-14 dioxide absorbed in hot barium hydroxide. The precipitated barium carbonate-¹⁴C was counted in a calibrated 2 π -flow counter using argon/methane (90 : 10) as the flow gas. The insoluble plant residues were ground to a fine powder and also converted into barium carbonate-¹⁴C by combustion in oxygen as above. The activity of the barium carbonate in this case was measured with an end-window counter.

The results of a typical series are presented in Table 1.

The figures are erratic, and we consider that experimentation on a larger scale than we were able to undertake is called for to achieve results which will be statistically more than roughly quantitative. We wish, however, to direct particular attention to the figures in the last column, which show the atropine activity by comparison with the soluble activity, both derived solely from the single initial dose of carbon-14 dioxide. A pronounced maximum is shown at 20–25 days, and a less pronounced maximum at 5–10 days. The total soluble activity, however, reaches a maximum within a few hours and thereafter decays, roughly exponentially, to about 40 per cent at 7–10 days and 20 per cent at 21 days, of the initial value. The total insoluble activity at first increases rather slowly and then falls off.

We think that these results of a preliminary investigation are relevant to the question of whether the biogenesis of atropine (or indeed of alkaloids generally) is an 'upgrade' process from small molecules or a 'downgrade' process from larger molecules⁴. In conjunction with published results from precursor studies⁵, they lead us to suggest that both processes are involved but that a 'downgrade' process plays the greater part, since the maximum atropine labelling appears so long after the activity and specific activity of the soluble carbon-14 have passed their maximum values.

These experiments arose from what was originally planned to be a series of experiments with labelled

precursors to obtain evidence on the theories put forward by Robinson^{6,7}. Some biosynthetic atropine-¹⁴C was desired in the first place to investigate the rate of turnover in the plant, and we were surprised to find that a fairly long period was required to produce appreciable labelling from a dose of carbon-14 dioxide. Evidence on this rate of turnover is still lacking. We have, however, fed methylamine-¹⁴C hydrochloride (1 mc., 3.6 mgm. in 180 ml.) via the roots of *Atropa belladonna* plants and extracted the atropine after nine days. Although the amine was readily taken up by the plant, the atropine activity (in $\mu\text{C./gm. dry weight}/\mu\text{C. of activity remaining in the plant}$) was only 37×10^{-6} . This comparatively low figure suggests that methylamine as such is not in fact directly incorporated in the biogenesis of atropine.

We believe that the method of a single dose of carbon-14 dioxide followed by normal growth and periodic analysis might profitably be more widely used in problems of this kind, since it offers the closest possible approach to normal physiological conditions in tracer experiments. It is susceptible of refinement in that the relative labelling in different carbon atoms might be determined after various growth periods. It is a complicating feature of atropine that the tropine and tropic acid moieties doubtless arise by different biogenetic paths and no doubt become labelled at different rates, although as yet we have not investigated this point.

We thank Dr. W. P. Grove for his interest in this work and one of us (E. A. E.) thanks the United Kingdom Atomic Energy Authority for the award of a Harwell fellowship (1955–58).

BIOLOGY

Prolonged Survival of Human Sperm in chemically defined Media at Room Temperatures

It has been pointed out that mammalian sperm represents an ideal tissue for exploring, under well-defined conditions *in vitro*, the intricate biochemical and physiological mechanisms underlying the viability and senescence of living cells¹. Efforts to move in this direction have been restricted by the necessity of having to maintain mammalian sperm in complex, undefined media and at temperatures which suppress metabolic activity.

Our success with the maintenance of functionally and metabolically active bovine spermatozoa at room temperatures² prompted us to investigate the possibilities of sustaining human sperm at close to physiological temperatures in various chemically defined maintenance media. Of all the media tested, medium 199 (Morgan, Morton and Parker³), a product of Hyland Laboratories in California, provided human sperm with the most satisfactory and compatible environment, which was capable of supporting their survival and activity for several days at room temperatures ($25 \pm 2^\circ \text{C}$).

The procedures employed were as follows: Semen collected from human donors was pooled immediately after liquefaction. The spermatozoa were washed free of seminal plasma by centrifugation (700*g* for 15 min.). After washing twice in the medium under investigation, the final volume was adjusted to give a concentration of 5–10 million cells/ml. of sterile medium. All media tested contained the following additives in final concentration: 31 mgm./100 ml. penicillin (sodium), 68 mgm./100 ml. dihydrostreptomycin sulphate, 300 mgm./100 ml. sulphanilamide, 4 units mycostatin per ml. and 150 units aqueous solution of sterile catalase (Worthington Biochemical Corporation) per ml. The suspension of human sperm was poured into small, sterile plastic vials, filled as completely as possible and stored in the dark⁴ at room temperatures. Initially and daily afterwards, separate unopened vials were removed, inverted several times to provide a uniform suspension of cells and measurements taken to assess motility and viability. The concentration of live sperm was determined by means of the eosin-nigrosin differential staining technique⁵. The vigour of the progressive motility was rated by means of an arbitrary scale graduated from 0 (no motility) to 5 (excellent progressive motility). The number of motile cells was calculated by killing and counting all the dead, non-motile cells in one haemocytometer and counting the non-motile cells in a second haemocytometer. The difference between these two counts represented the concentration of motile sperm in the population. pH measurements were taken at various intervals during the experiment.

Table 1 summarizes the results of three replicate experiments. The number of live and progressively motile cells suspended in medium 199, buffered with 0.02 *M* tris, remained relatively constant for five days. It should be noted that medium 199 buffered with bicarbonate and carbon dioxide did not sustain cell viability as well as media buffered with tris or phosphate.

The pH of the tris-buffered 199 sperm suspension, initially 7.1, was usually lowered 0.1–0.2 of a pH

Table 1. EFFECT OF TRIS-BUFFERED MAINTENANCE MEDIUM 199 ON MOTILITY AND SURVIVAL OF HUMAN SPERMATOZOA KEPT AT ROOM TEMPERATURES FOR SIX DAYS

Age of sperm (days)	Live (per cent)	Motile (per cent)	Quality of motility*
0	60	67	3.5
1	58	64	4.0
2	52	51	3.5
3	55	54	3.5
4	49	55	3.5
5	45	50	3.5
6	34	37	3.0

* 0 (non-motile), 1 (vibratory), 2 (poor progressive), 3 (fair progressive), 4 (good progressive), 5 (excellent progressive).

unit on the fifth day of storage. Changing the medium on the third or fifth day of storage did not appreciably affect the time of survival of the sperm. However, the slight increase in alkalinity of the fresh medium noticeably increased the vigour of their translocatory motion. The introduction of a small amount of egg yolk (0.5–1.0 per cent) into the medium significantly enhanced both the progressive motility and the survival time of these cells.

This technique makes possible a more comprehensive investigation into the metabolic and functional behaviour of young and aged post-mitotic human cell populations, under well-defined and rigidly controlled conditions.

The work was supported by grant RG-6339 from the National Institutes of Health and is published with the approval of the director of the West Virginia Agricultural Experiment Station.

Development of the Electric Organ of Mormyridae

THE existence of striated myofibril structures persisting in the electroplaques of adult fish had led several authors^{1–3} to consider muscle as the tissue of origin of the electric organs of Mormyridae, but no data have been published to justify this assumption. Recently I have presented circumstantial evidence showing indirectly that the electric organ of the Mormyridae does in fact arise from the deep lateral muscle⁴; however, direct experimental evidence was still lacking.

Through the courtesy of M. J. Daget, head of the Hydrobiological Laboratory of the Institut Français d'Afrique Noire, Diarafabé, Sudan, I had the opportunity of examining a batch of young Mormyridae and am now able to provide direct evidence on the origin and ontogenetic development of the electric organ of these fish.

As is well known, all species of the family Mormyridae possess two pairs of organs situated symmetrically on each side of the vertebral column between the caudal, dorsal and anal fins⁵. In the adult fish each organ is composed of a single series of electroplaques,

Fig. 1. Longitudinal sections of tails of three Mormyridae. A, *Mormyrops deliciosus* (120 mm.) adult; B, *Hyperopisus occ.* (24.5 mm.); C, *Mormyrus rume* (24.5 mm.); both young. Haematoxylin-eosin stain. Scale, 1 mm.

which are juxtaposed and are variable in number, 40-200 according to the species. The electroplaques are of the same size and are situated perpendicularly to the longitudinal axis of the fish. The very regular disposition of the electroplaques (Fig. 1A) seems to indicate that the organ arises from a special centre.

However, longitudinal histological sections of the tail of a very young *Mormyrus rume* (Figs. 1C and 2A) show that the electric organ, which is of uniform structure in the adult, is here composed of about ten groups of electroplaques. Each group is situated within a single myomere and occupies only the portion adjacent to the vertebral column. The plaques are arranged perpendicularly to the myoseptal wall in the same way as the muscle fibres. The nerve trunk is situated in the myosept and the nerve fibres penetrate only between those electroplaques which are situated in the myomere anterior to the myosept; only the caudal surfaces of the electroplaques receive nerve endings.

Although the organ is not fully developed, the majority of the electroplaques have their final aspect: double electroplasmic wall in the form of an envelope, enclosing a non-electroplasmic striated structure; the surface of the posterior wall has cylindrical prolongations (pedicles) of which only the extremity is surrounded by nerve endings.

However, in the neighbourhood of the intact fibres of the myomeres which form part of the organ, electroplaques in different evolutionary stages may be seen: for example, in one case, the electroplasm is fully formed, but does not yet possess any pedicles; the plaque is still oval and the interior is often markedly striated. In other cases, the electroplasm is only partially formed; it is rich in nuclei and surrounds the caudal part of a bundle of muscle fibres of which the cranial extremity is still attached to the myosept. The striation of these muscle fibres is clearly visible, although it is less strongly coloured than that of the neighbouring muscle tissue.

The following preliminary conclusions can be drawn from these observations: (1) The electric organ of *Mormyrus rume* arises from several myomeres; (2) the electroplaques of these organs develop from striated muscle fibre already formed; (3) in contrast to the electroplaques of *Gymnarchus niloticus* (family Mormyridae), those of *Mormyrus rume* are formed from the muscle tissue of a single myomere; (4) the pedicle is probably formed during a later stage of the development of the electroplaque; (5) the innervation is of monoseptal origin.

We have also shown the plurimyomeric origin of electric organs in other species of Mormyridae; thus in the organ of a *Hyperopisus occidentalis* (24.5 mm. in length) (Figs. 1B and 2B) and a *Mormyrops deliciosus* (38 mm. in length), the myomeric segmentation is still evident. These two fishes were older than the *Mormyrus rume* previously described, and all their electroplaques are at the same stage of development; they still show, however, a marked difference in comparison with electroplaques of the adult fish, which in these two species present a peculiarity. In contrast to *Mormyrus rume*, in which the anastomizing pedicles are fused on to the surface of the electroplaque nearest to the pedicle, the pedicles of the adult *Hyperopisus occidentalis* and *Mormyrops deliciosus* pierce and traverse the electroplaque and fuse on to the surface which is opposite to the pedicle⁶. We also know that excitation arriving from the extreme point of the pedicle is propagated towards the electroplaque and is distributed in the first place over the surface of the electroplaque opposite to the pedicle (Szabo, Th., unpublished observations).

Fig. 2. A, Higher magnification of Fig. 1C. B, longitudinal section of the electric organ of *Hyperopisus occ.* In both cases the myomeric segmentation is still evident. Haematoxylin-eosin stain. Scale 0.5 mm.

Fig. 3. Oscillographic recording of the electric activity of a *Mormyrops delicosus* (38 mm.); electric activity of the resting animal (first three recordings) interrupted (arrow *St*) by cutaneous stimulation, provoking an acceleration of the spontaneous emission.

In the very young fish, although the electroplaques already possess their long pedicles and these their nervous endings, the pedicles are attached to the surface of the electroplaque nearest to the pedicle and do not traverse the electroplaque. Accordingly, microscopic examination reveals no discontinuity in the electroplaque. Oscillographic recordings also prove that in these young electroplaques, which already function (Fig. 3), it is the surface nearest to the pedicle which is initially active and not the opposite surface, as in the adult.

In summary, there seem to exist three stages in the development of the pedicled electroplaques of Mormyridae: (1) formation of the electroplasmic tissue; (2) consecutive rapid appearance of the pedicle and its innervation; (3) piercing of the electroplaque, occurring in certain species at a later stage of development.

The Manatee: Ecology and Use for Weed Control

SINCE 1885 the Botanic Gardens in Georgetown, British Guiana, has had in some ornamental pools manatees (*Trichechus manatus*, order Sirenia), which have been always fed with grass by visitors. These pools have been kept clear by the manatees and it seemed always necessary to get additional food in the form of grass. It was therefore felt that experiments should be proceeded with using these animals for weed control, and some have been maintained in the reservoirs of the water purification plant and have effectively kept these clear of aquatic plants, particularly *Cabomba aquatica*, *Anacharis*, *Leersia*, *Utricularia*.

We have since found that the manatee is not merely an occasional but also a very voracious and determined grass feeder, which can in fact clear trenches which are covered with grass or *Nymphaea*, *Nelumbo*, *Eichornia*, as well as submerged aquatics, and they have been doing a very commendable job in con-

fined areas. During 1959-60 several experiments were carried out, and it has been found that two manatees 7½ ft. long were capable of clearing a canal 22 ft. wide and 1,600 yd. long in 17 weeks. They will also keep it clear of weeds to allow the free passage of water and will break any wood barrier fixed across the canal in order to get at grass beyond the barrier. These animals are not numerous, they are perfectly docile, easily bruised and seemingly very slow in reproduction. I have collected 46 of them to date, and they have been distributed in several canals of drainage and irrigation schemes throughout the country. They are found in the rivers of British Guiana and are caught by fishermen in seines, but can easily be drowned.

Much information has been collected on their anatomy through the University of Florida and much more information is desired on their ecology and reproductive habits. I would like to have any further information available. I have already had inquiries from Ceylon, Thailand and Malaya as to the prospects of the use of these animals in those countries for weed control of the water hyacinth and other aquatic plants which are a costly nuisance.

As a means of water-weed control, the use of these animals is far more effective and lasting than the usual chemical weedicides. They are harmless to fishes and other water animals, and are seemingly unaffected even by electric eels which are normal inhabitants of some of the irrigation canals into which these manatees were introduced. The only risk in their wide use is that they may be slaughtered for their meat; legislation is now being enacted to ensure their complete protection.

A full account of ecological work on these mammals will shortly be published.

Equivalent Pore Radius in the Axolemma of the Giant Axon of the Squid

PREVIOUS work^{1,2} on the fine structure of the giant nerve fibre of the squid has revealed the existence of slit-like channels ~60 Å. wide by ~5.3 μ long traversing the Schwann cell along a tortuous path the total length of which is ~4.3 μ. The axolemma itself is surrounded by a space ~83 Å. wide. It has been demonstrated that no effective osmotic pressure can be developed across the Schwann cell layer. Hence the axolemma appears to be the barrier for osmotically induced flow into the axoplasm.

The present communication deals with the determination of the reflexion coefficient σ of the axolemma for a set of non-electrolytic molecules of small radii. The σ values were then used (based on the principles developed by Durbin, Frank and Solomon³, Durbin⁴ and Solomon⁵) to calculate an equivalent pore radius for the axolemma in resting condition.

The giant nerve fibre from the first stellar nerve of the squid *Doryteuthis plei* was used. The technique and equipment were the same as those previously described². The experiments were carried out at 23° C.; they consisted in measuring the volume changes of the axon, initially in artificial sea water (1,010 mOsm./l.)⁶, and at various time-intervals after

this medium had been removed and replaced by a test solution. Test solutions were prepared by adding a known amount of non-electrolyte, usually 60, 230, and 480 mOsm./l., to artificial sea water made hypotonic (780 mOsm./l.) by the subtraction of 230 mOsm. of sodium chloride per litre. The cryoscopic point of a solution that has a concentration of 1 Osmol. per kgm. of water is -1.858°C . The probing solutes were methanol, formamide, ethanol, urea, ethylene glycol and glycerol. Their molecular radii were obtained from Fisher-Hirschfelder-Taylor models (Table 1).

Table 1. REFLEXION COEFFICIENT OF THE AXOLEMMA FOR THE TEST SOLUTES

Solute	Molecular radius (Å.)	No. of experiments	Mean $\sigma \pm \text{S.E.}$
Methanol	1.83	7	0.35 ± 0.03
Formamide	1.96	5	0.44 ± 0.02
Ethanol	2.13	5	0.63 ± 0.03
Urea	2.17	4	0.70 ± 0.03
Ethylene glycol	2.24	3	0.72 ± 0.03
Glycerol	2.77	4	0.96 ± 0.02

The rate of volume change per unit area may be described by the following equation:

$$dV/A \, dt = L_p \Delta\pi_i - \sigma L_p RT \Delta c_s \quad (1)$$

in which L_p is a phenomenological coefficient⁷, $\Delta\pi_i$ the osmotic pressure difference of non-penetrating solutes, R the gas constant, T the absolute temperature, Δc_s the concentration difference of the penetrating solute, and σ the reflexion coefficient^{8,9}. σ measures the ability of the membrane to discriminate between the particular permeable solute used, and the solvent. It is considered that osmotic balance exists across the membrane when the rate of volume change at zero time is zero. From equation 1, it can be shown that:

$$\sigma = (\Delta\pi_i/RT)/\Delta c_s, \text{ when } dV/A \, dt = 0 \text{ at } t = 0 \quad (2)$$

The osmolar concentration difference of the penetrating solutes which equilibrate a $\Delta\pi_i/RT$ of 230 mOsm./l. for the six different test solutes was determined by graphic interpolation, and afterwards σ by using equation 2 (Table 1). As expected, σ is found to depend on the radius of the solute molecule.

Durbin, Frank and Solomon³ have suggested, and later Durbin⁴ has demonstrated, that $\sigma = 1 - A_{sf}/A_{wf}$, where A_{sf} and A_{wf} are the effective pore areas available for filtration of the solute and solvent molecules respectively. Renkin's¹⁰ equation 19 shows that A_{sf} , the effective pore area for the passage of a molecule x , is equal to:

$$A_{sf} = A_p [2[1 - (r_x/r_p)]^2 - [1 - (r_x/r_p)]^4] \quad (3)$$

in which A_p is the geometrical pore area, and r_x and r_p are the radii of the molecule and the pore respectively. Dividing equation 3 for a given solute (s) of known radius (r_s) by the same equation for the water molecule (the radius for water, r_w , was taken as 1.5 Å.¹¹), the ratio A_{sf}/A_{wf} may be determined for any r_p value.

Our experimental values for $(1 - \sigma) \pm$ one standard error plotted as a function of the molecular radius can be fitted by a curve which corresponds to an equivalent pore radius of 4.25 Å., as is shown in Fig. 1. The uncertainty in fitting the curve is ± 0.25 Å. The present result is independent of the nature of the path of the ions across the axolemma.

Fig. 1. Experimental values of $(1 - \sigma) \pm \text{S.E.}$ for the axolemma, plotted as a function of the molecular radius. These values are fitted by a curve corresponding to an equivalent pore radius of 4.25 Å. The uncertainty in fitting the curve is ± 0.25 Å.

The presence of pores with a 4.25 Å. radius indicates that the axolemma is the membrane across which the ionic gradient necessary for nerve activity is maintained.

We are indebted to Prof. A. K. Solomon for helpful discussions during his stay at the Institute; and to Dr. Guillermo Whittembury, Dr. Richard P. Durbin, and Dr. Leopoldo Villegas for critical comments regarding this work.

Transport of Phosphorus by Fungal Mycelium

TRANSLOCATION of nutrients by fungal mycelium has been reported by Schutte¹ and by Grossbard and Stranks². Attempts in this Department to determine the rate of transport of phosphorus using a tracer technique have, however, indicated that the mycelium of *Phycomyces nitens*, *Absidia glauca* and *Chaetomium*

spp. is only able to transport phosphorus-32 under certain limited conditions.

The experimental procedure is to pour a synthetic agar medium plus 2 per cent glucose into Petri dishes and then to remove, aseptically, a 5-mm. wide channel along a diameter of the Petri dish. The organism is inoculated in the centre of one of the halves of the medium and grows over the channel to form a hyphal bridge between the two halves. Potassium dihydrogen phosphate, labelled with phosphorus-32, can be added to either the inoculated or the uninoculated half of the agar culture by removing a disk of agar with a cork borer and dropping the labelled solution into the well so formed. To sample, 5 mm. square portions of the agar bearing the mycelium were removed, dried on planchettes under an infra-red lamp, and counted.

The results showed that there was no translocation of phosphorus through established mycelium either from the inoculated side to the colonized side of the culture or in the reverse direction, that is, from the younger to the older part of the mycelium. The only condition under which it was possible to show transport of phosphorus in appreciable amounts was where the solution containing labelled potassium dihydrogen phosphate was added to the inoculated side of the Petri dish before growth of the mycelium over the channel had ceased. In these circumstances the mycelium takes up phosphorus which is carried by the extending hyphae.

It seems clear, therefore, that a distinction needs to be made between translocation through established mycelium independently of the growth of the hyphae, as in the case of movement of dyes reported in *Armillaria mellea*, *Collybia velutipes* and other agarics by Schütte¹, and transport by the uptake of material at one site and its transference in the mycelium to another site due to hyphal extension, as in the case of phosphorus reported here, and cobalt and caesium transport referred to by Grossbard and Stranks². That transport of phosphorus is via the extending mycelium itself has been confirmed in the case of *Chaetomium* sp. by transferring mycelium which had been grown on phosphorus-32 labelled medium to potato dextrose agar containing no phosphorus-32. The resultant colony consisted of mycelium which was shown both by auto-radiographs and by counting to contain phosphorus-32 up to its margin. No activity was apparent beyond the edge of the colony, indicating that phosphorus so absorbed into the mycelium does not exchange appreciably with the phosphorus present in the medium nor diffuse out into it.

GENETICS

White Band, a New Spotting Mutation in the Syrian Hamster

THE first mutation reported in the Syrian hamster, *Mesocricetus auratus*, was a recessive type of white spotting which has been designated as piebald¹. The new mutation to be described here differs from piebald in two respects: (1) the mutation is inherited as a

Fig. 1. Three types of white spotted hamsters; the white band (left) and the piebald (right); the central animal is genetically both white band and piebald. The only interaction observed for the two forms of white is for a broadening of the medial band

dominant to normal pigmentation; and (2) the characteristic spotting pattern produced by the mutation is phenotypically distinguishable. The new mutant gene has been termed 'white band' and has been given the symbol *Ba*. The gene was discovered in the United States in 1957, and stock carrying the gene was imported into Britain during 1959.

With the piebald type of spotting, the white and coloured areas of the coat are greatly intermingled. There is invariably a streak of white extending from the muzzle to between the eyes. However, with the new spotting, the white areas are confined to the trunk region of the body, are not broken up to a great extent and have not been seen to occur on the head at all (see Fig. 1). The middle specimen of the photograph is a genetic combination of the two mutant genes and phenotypically displays features of both: a median band of white, which is typically wider than that of an ordinary white band, white on the forehead together with a white brindled posterior.

An imported white band male was paired with normal females, producing an F_1 of 46 white band and 43 normal offspring. An F_2 generation from the F_1 white band consisted of 90 white band and 21 normal. A backcross of the F_1 to the normal gave 79 white band and 91 normal young. A χ^2 analysis, on the assumption that the gene is assorting in exactly 50 per cent of cases from its normal allele and that the various genotypes are of normal viability, yields $\chi^2_1 = 3.14$ ($P > 0.30$). This value may be partitioned into a gene segregation χ^2_1 of 0.20 ($P > 0.50$) and heterogeneity between the three generations of $\chi^2_2 = 2.94$ ($P > 0.20$). There is the possibility that the white band gene may be lethal when homozygous, but the frequencies of the two phenotypic classes in the F_2 are a poor fit to the 2:1 ratio which would be expected for this eventuality ($\chi^2_1 = 10.82$; $P < 0.01$).

The mutant gene derives its name from a band of white which in many individuals either completely, or almost completely, encircles the body. However, the expression of the band is variable, and in a great many animals may be partially or completely interrupted by a spinal stripe of pigment, as appears on the white band shown in Fig. 1. In high-grade animals, the band is extremely wide, the belly is almost completely white, and the areas of pigmentation

tion are restricted to the head, shoulders and lower hindquarters.

At birth the ear auricula of most white band animals are pink, but in adult animals only the basal portions of the auricula remain depigmented. The melanism in the skin around the genitalia of both sexes is suppressed.

It is possible that the gene may not be completely dominant, since the mean percentage of white in the coat of heterozygotes, *Baba*, is less than that of homozygotes *BaBa*. The mean for the white band animals of the F_1 is 15.87 ± 0.75 per cent, for the backcross (*BC*) is 16.34 ± 1.10 per cent and for the F_2 is 23.68 ± 1.3 per cent. The F_1 and *BC* means are in good agreement, as could be anticipated, since the white bands in both generations are necessarily *Baba*. In the F_2 , however, one-third of the white band animals are expected to be homozygotes and, if these possess more white than the heterozygotes, the value of the mean may be expected to be raised.

This may be the case, for the mean of the F_2 is significantly higher than the means for the other two generations. The frequency distribution of percentage of white, moreover, is unimodal and positively skewed. This would appear to indicate that, if the *Ba* gene is incompletely dominant, it is so in the stochastic sense that the higher-grade animals are more likely to be *BaBa* than *Baba*. A comparison of the frequency distribution of the F_1 , *BC* and F_2 would indicate that the critical point is in the region of 35 per cent white. In the F_2 , 13 per cent of the white band animals have more than this amount, whereas in neither F_1 nor *BC* did a white band approach this amount of white.

The F_1 offspring were the young of a single male, and the *BC* and F_2 generations were analysed for an association with sex. The frequencies for the *BC* are 23 ♂♂ *Ba*, 23 ♀♀ *Ba*, 17 ♂♂ *ba* and 26 ♀♀ *ba*, which yields a χ^2_1 for independent assortment of 0.84 ($P > 0.30$). The F_2 classified for sex are 39 ♂♂ *Ba*, 51 ♀♀ *Ba*, 11 ♂♂ *ba* and 10 ♀♀ *ba*, producing an associative χ^2_1 of 0.68 ($P > 0.03$). These results indicate that the *Ba* gene does not show partial sex linkage.

In summary, the white band trait in the hamster behaves in heredity as a dominant, monogenic, autosomal entity.

I wish to thank Mrs. Margaret Beher for her assistance in obtaining specimens of white band hamsters.

Genetic Recombination in a Common-B Cross of *Schizophyllum commune*

THIS communication reports the synthesis of stable common-B heterokaryons in *Schizophyllum commune*, and the occurrence of normal genetic recombination in fruit-bodies derived therefrom. Although common B heterokaryosis and the normal segregation of the A-factor in common-B fruit-bodies have been reported in other tetrapolar species¹⁻³, these phenomena in *S. commune* have not been demonstrated with certainty^{4,5}. The nature of production of spores in such fruit-bodies, however, has not been

fully determined, and "It appears uncertain whether such fruit-bodies are apomictic or functionally bipolar"⁶.

Stable common-B heterokaryons of *S. commune* have been established by three methods:

(1) 'Illegitimate' Buller phenomenon, for example:

$$(A^{11}B^{41}p^ru_1n_2 + A^{12}B^{2p}su_1n_2) \times A^{12}B^{41}p^su_1n_2 \rightarrow (A^{11}B^{41}p^ru_1n_2 + A^{12}B^{41}p^su_1n_2)$$

(p^s , p^r , polymyxin sensitivity and resistance, respectively; u , n , ad , arg , uracil, niacin, adenine and arginine, respectively).

(2) Isolation from the region of confluence of mated homokaryons, for example, $A^{11}B^{111} \times A^0B^{111}$.

(3) Nutritional selection on minimal medium from the region of confluence of mated homokaryons, for example, $A^{11}B^{42}arg_1ad_2n_3 \times A^{12}B^{42}arg_2ad_1n_3$. In all cases, two successive transfers of single apical cells were made to ensure the establishment of single mycelia.

The common-B heterokaryotic genotypes have been confirmed in all cases by mating type-tests with homokaryons, and in (1) also by the pattern of growth of the heterokaryons and of the resulting backcrossed dikaryons on various types of supplemented media, and the recovery of the individual homokaryotic component strains.

In culture, the common-B heterokaryon resembles a somewhat thin and irregular dikaryon and has relatively little aerial growth. The hyphae are irregularly branched, and the septa are commonly provided with pseudoclamps, that is, incompletely clamp-connexions, the tips of which fail to fuse with the sub-terminal cells and often continue to grow to give side branches; these typically have pseudoclamps. As observed with phase microscopy, the number of nuclei per cell is 1-5. Secondary septation and the production of side branches seem to reduce the number of nuclei per cell, and these processes may account for the homokaryotic hyphae that often grow to form distinct sectors. Preliminary results of the isolation of hyphal-tips and of the examination of mycelia grown from fragments following maceration give significant indication that the hyphae lacking pseudoclamps are homokaryotic, whereas pseudoclamps appear to be reliable indicators of heterokaryotic hyphae.

Common-B heterokaryons constituted of non-allelic, biochemically deficient strains grew normally on minimal medium: genetic complementation operates as in the dikaryon.

Small plugs of mycelium⁵ taken from common-B matings of the type described in (3) gave growth on minimal medium only when taken from the area of confluence of the two strains: nuclear migration either does not occur at all, or it is severely restricted to a distance of no more than 2 mm.

In further analysis, two patterns of behaviour of the B-factor has been found.

(1) Nine independent heterokaryons of the composition $(A^{12}B^{41}p^su_1n_2 : A^{11}B^{41}p^ru_1n_2)$ were inoculated on fruiting medium in replicate sets of ten; fruiting bodies appeared in only a single culture about two months after inoculation. Small pieces of tissue isolated from the sterile portions of one of these fruits gave rise to a normal dikaryon, which by mating tests with homokaryons was found to be $(A^{12}B^{41}p^su_1n_2 + A^{11}B^{41}p^ru_1n_2)$. Among a sample of 177 monosporous progeny, there were 102 B^{41} and 75 B^* ; a sample of 120 progeny was tested for

five additional pairs of markers (A_a , A_β , p , u n) and showed the segregation expected from regular meiosis in the diploid basidium. A test cross, $A^2B^* \times A^{41}B^2$, gave among 150 progeny 80 B^* and 70 B^2 —but no recovery of B^{41} . All the B^* isolates of this cross had the 'flat' morphology typical of the common- A heterokaryon, and from these it proved to be impossible to recover morphologically homokaryotic mycelia, either by the isolation of single terminal cells or by deheterokaryotization by treatment with polymyxin. Together with the data on segregation, these results rule out the possibilities of disomic or heterokaryotic spores, and contamination as explanations of the 'flat' morphology. B^* is compatible with all 57 distinct B factors in the collection of these Laboratories; this includes B^{41} , only with which, however, B^* gives an anomalous reaction: irregular, patchy and delayed dikaryosis.

It therefore seems evident that these 'illegitimate' fruit bodies appeared as the result of a spontaneous mutation within the B^{41} , which led to a new B specificity and to spontaneous common- A heterokaryosis. The latter might be interpreted in two ways: (a) the new B factor is non-functional, therefore $A^2B^* \equiv (A^2B^1 : A^2B^2)$; (b) the new B is itself unstable and occasionally yields a derived factor, $A^2B^* \rightarrow (A^2B^* : A^2B^{**})$. Swieczynski and Day recently reported the "segregation of a new B reaction" in comparable fruits of *Coprinus lagopus*³.

(2) A single, tiny fruit-body appeared on a common- B heterokaryon of the constitution ($A^{42}B^{42}arg_6ad_2+n_3 : A^{41}B^{42}arg_6+ad_2n_3$). This fruit-body was very similar to the aberrant fruit-bodies that sporadically appear on homokaryons. All segregants of a sample of 150 progeny that were tested, however, showed only B^{42} , but five other pairs of markers showed independent assortment and crossing-over as expected from normal meiosis.

When these results are compared with previous reports in the literature, it becomes apparent that the tetrapolar fungi, as a general phenomenon, have two kinds of hemicompatible heterokaryons: (a) the common- A heterokaryon is initiated by extensive nuclear migration and is characterized by depressed growth of a mycelium composed of hyphae having simple septation⁴⁻⁵; (b) the common- B heterokaryon is synthesized without nuclear migration and only in the region of confluence of mated homokaryons and is characterized by the normal growth of a mycelium composed of hyphae provided with pseudoclamps. The 'illegitimate' common- B fruit-bodies must have a normal diploid stage; therefore, they are not 'apomictic', but 'functionally bipolar'.

The results of this work will be reported in detail elsewhere.

SOIL SCIENCE

A Plate Method for studying the Breakdown of Synthetic and Natural Silicates by Soil Bacteria

In a previous communication¹, a plate method for detecting phosphate-dissolving micro-organisms in soil was described. We have now found that a similar technique can be used for work on the breakdown of silicates by soil micro-organisms. For this purpose the insoluble silicates are ground in a ball mill and directly incorporated into molten agar as described for the insoluble phosphates¹.

Fig. 1 shows a number of plates prepared in this way using synthetic and naturally occurring silicates. The synthetic calcium, zinc and magnesium silicates were found to be amorphous to X-rays, but the minerals wollastonite, apophyllite and olivine gave X-ray powder diffraction patterns which showed them to be substantially free of impurities. The test organism used here was an unidentified species of *Pseudomonas* isolated from soil, and the clearing around the growth can be clearly seen.

It has already been shown by Duff and Webley² that 2-ketogluconic acid is produced by similar soil organisms when grown in liquid culture containing insoluble phosphates and silicates. The presence of this acid in the clearer zone around the growth in the present work was demonstrated by cutting out an agar disk (3 mm. diameter) close to the growth and applying it to a paper chromatogram and allowing it to dry at room temperature. The dried disk of extracted agar could then be brushed off and when the chromatogram was developed and sprayed, as described previously², 2-ketogluconic acid could be easily detected. Calcium, zinc and magnesium could usually be detected as their soluble chelates by spraying with 8-hydroxyquinoline³.

The clearer areas containing the residues of the naturally occurring minerals (wollastonite, apophyllite, and olivine) were carefully cut out and the agar was melted in hot water. The solutions were then centrifuged to sediment the insoluble residues, which on examination were found to be amorphous by X-rays. The insoluble material from the surrounding

Fig. 1. Decomposition of synthetic and natural silicates by a soil bacterium. The basal medium was that used previously (ref. 1) but containing 2 per cent w/v glucose. The final concentration of the silicates was 0.25 per cent w/v. After inoculation, the plates were incubated for 4 days at 25°.

cloudy zones was also extracted in the same way and gave X-ray diffraction patterns identical with those of the original powders. These results clearly showed that the crystal structure of the minerals had been destroyed.

Some Effects of Aldrin and DDT on the Soil Fauna of Arable Land

INSECTICIDES are now extensively applied to agricultural soils, and if this practice continues there is the obvious possibility that such treatments may have harmful effects on the soil fauna. The chlorinated hydrocarbons are not readily broken down in soil^{1,2}, and the general use of fertilizers containing aldrin could be one source of accumulations of this material in agricultural land. The applications of insecticide may control specific pests as desired, but could also suppress certain elements of the fauna, and even cause secondary increases of some soil animals by modifications in the predator pressure.

We have studied the effects of rates of insecticides commonly used, on the soil fauna of arable land, at Cannington Farm Institute, in Somerset. The rates of insecticides used were 3 cwt. of 1.25 per cent aldrin dust, and 2 cwt. of 5 per cent DDT dust per acre, and plots were laid out in a random block consisting of four replicates of each treatment and control. The size of each plot was 6 ft. square with 6 ft. guard rows between plots. The insecticides were applied to the surface of the plots as dusts and thoroughly mixed into the soil to a depth of 6 in. by double rotovation. All plots were kept fallow throughout the period of the trial by regular application of the weed-killers CMPP and 'Dalapon'.

The soil was sampled at intervals of 2-3 months after the beginning of the experiment. Samples taken from each plot consisted of (a) four 2-in. diameter cores to a depth of 6 in., and (b) twenty-five 1-in. diameter cores also 6 in. deep. The fauna was extracted from the first sets of samples by washing through a somewhat modified Salt and Hollick³ apparatus and then stored in vials of alcohol until the animals could be sorted into taxonomic categories by examination under a binocular microscope. The second set of samples from each plot was bulked and thoroughly mixed, and the nematodes extracted from small subsamples placed in Baerman funnels⁴.

Considerable changes in population occurred in most groups of the soil fauna. Initially numbers of most groups of animals decreased because of the cultivation, but this lasted for only three months. Both insecticides significantly decreased the numbers of *Acarina* in the treated plots. Aldrin also brought the population of *Collembola* to a low level, but DDT increased numbers of these animals to a peak nine months after treatment, after which numbers fell to a level slightly above that of the untreated plots. This confirms the results obtained by Sheals⁵ for soil treated with DDT and then planted with rye grass,

Fig. 1

and by Dobson⁶, who found the *Collembola* population increased in arable land treated with BHC. The numbers of dipterous and coleopterous larvae and pupae, thrips, pauropods and symphylids were all markedly suppressed by both insecticides. Numbers of root aphids were greatly decreased by aldrin but not by DDT; neither insecticide affected the populations of small plant parasitic nematodes, earthworms and enchytraeid worms to a significant extent.

More detailed sorting of the fauna, possibly to species-level, will be necessary to show whether the increased numbers of *Collembola* in the DDT-treated plots result from changes in the predator-prey balance, but quite small dosages of insecticide can obviously have considerable effects on the fauna and so might eventually influence the fertility of the land.

A full account of the results will be published shortly.

Microbiology of Some Soils from Antarctica

ANALYSES of soil from Antarctica reveal little weathering and only minute quantities of organic matter¹. Vegetation in this area is commonly restricted to mosses, lichens, or algae. A number of samples of moss, algae and soil from the McMurdo Sound region have been examined to determine the nature of the microflora and microfauna associated with this very simple organic cycle.

Among the genera of terrestrial algae already identified are *Chlamydomonas*, *Chlorella*, *Chlorococcum*, *Stichococcus*, *Nostoc*, *Hantzschia*, *Bumilleriopsis*, *Radiosphaera*, *Heterothrix*, *Heterococcus*, all of which are typical of soils in temperate climates^{2,3}. The last-named four genera have not been previously recorded from the Antarctic continent.

The bacterial flora of the moss is similar to the epiphytic flora found in temperate climates^{4,5},

consisting largely of Gram-negative chromogens. The soil flora, however, appears to be more distinctive. There are more chromogenic bacteria than are normally found in soils, spore-forming bacteria are rare, and there is a large proportion of Gram-positive cocci. Attempts at isolating aerobic nitrogen-fixing bacteria were unsuccessful. Fungi are uncommon and *Streptomyces* have only been recovered from one site.

Ciliate protozoa identified include *Colpoda cucullus*, *Homalogastra setosa* and *Trichopelma sphagnetorum*, all typical soil forms^{6,7}, and a suctorian. Amœbæ are quite common, but testaceans have only been recovered from moss. Rotifers, tardigrades and nematodes were also present in some of the samples.

All these micro-organisms grew at room temperature, which in the case of the algae varied between 0° and 38° C. The bacteria grew both at 4° C. and at 25° C., but growth was slower at the lower temperature.

The presence of these micro-organisms, many of them typical of the soils of temperate regions, suggests the presence of an organic cycle comparable to that found in more developed soils and supports the view that the rock waste of this region may be properly referred to as soil.

Further details will be published elsewhere.

VIROLOGY

Inactivation of Virus Hæmagglutinins by para-Chloromercuribenzoic Acid

It has been found that a number of chemical agents reacting with thiol groups can impair the infectivity of certain viruses while leaving others unaffected^{1,2}.

In the course of a systematic study, one of these compounds, para-chloromercuribenzoic acid, has been tested for its effect on a number of virus hæmagglutinins.

It was found that substances in the media used to suspend the viruses did not abolish the effect of the compound in the concentrations used. The reagent dissolved in distilled water was mixed with equal volumes of virus suspensions and held at room temperature for 1 hr. The mixture was then dialysed at 4° against 0.1 M phosphate buffer, pH 7.2, except in the case of the arbor viruses, when borate saline, pH 9.0, was used³.

The dialysing fluid was changed at 4 hr. and the dialysis continued overnight. Doubling dilutions of the dialysates were made in plastic plates, 1 per cent cells added and allowed to settle at room temperature (occasionally 4° C.). Human cells were used for most tests, sheep cells for the E.M.C. group, goose cells

* Number of tests performed. —, Not tested.

for the arbor viruses and rhesus cells for adenovirus type 7.

The compound tested had no effect on red cell receptors⁴. The other results are shown in Table 1.

There seems to be a clear-cut division between viruses in which there is a marked destruction of hæmagglutinating activity and others which are unaffected even by high concentrations. The myxoviruses and arbor viruses seem to be unaffected while the enteroviruses and reoviruses (previously called ECHO 10) are inactivated. This may be a reflexion of a fundamental difference of structure between these groups. However, it can be seen that within the adenovirus group the results are not consistent and so caution would be required in using this reaction as an aid in classification. Another point of interest is that the effect of the compound on the infectivity of a virus may be quite different from that on the hæmagglutinin, for the infectivity of many myxoviruses is destroyed by this treatment whereas the infectivity of GD VII is unchanged.

Intranuclear Formation of Cytomegalic Inclusion Disease Virus

HUMAN cytomegalic inclusion disease virus has been isolated in human fibroblast cultures and its cytopathogenic properties characterized by Smith¹, Rowe *et al.*², Weller³, and Weller *et al.*⁴. The present communication deals with some appearances in the electron microscope. The strain used is the Kerr strain obtained from Dr. T. H. Weller which has been passaged in tissue culture about 20 times. The virus was grown in human embryonic skin-muscle fibro-

blasts⁵, the medium for both growth and maintenance being Earle's saline, 0.5 per cent lactalbumin hydrolysate, 10 per cent inactivated horse serum, soya bean trypsin inhibitor and antibiotics; the pH was adjusted with sodium bicarbonate to 7.2. For electronmicroscopy the medium was poured off and the cells fixed *in situ* with buffered osmic acid

Fig. 1. Electronmicrograph showing the formation of virus particles, each possessing a single surrounding membrane, within the nucleus of the cell. ($\times 40,000$)

Fig. 2. Electronmicrograph showing a cluster of virus particles lying close to the nuclear membrane. The latter, which is normally double, appears to be multiple over this area and shows inward extensions which are responsible for the formation around the virus particles of second and occasionally also third surrounding membranes. The large bodies in the cytoplasm are mitochondria. ($\times 44,800$)

Fig. 3. Electronmicrograph illustrating a walled-vacuole within the nucleus, containing virus particles. Inward extensions from the inner layer of the vacuole are continuous with membranes forming the outer coats of some of the virus particles. ($\times 37,500$)

for 1 hr. After dehydration through alcohol, the tissue was scraped off the glass and embedded in methacrylate. Thin sections were cut for examination.

The virus is formed in the nucleus of the cell. The earliest stage of virus formation as yet observed was that of masses of granular particles each possessing a single surrounding membrane (Fig. 1). The size of these particles is 80–120 m μ . Virus particles lying free in the cytoplasm, on the other hand, possess double membranes, the outer of which is acquired during passage through the nuclear membrane. There appeared to be two methods of passage into the cytoplasm. Many particles pass through the nuclear membrane singly (Fig. 2), and at such sites of passage there occurs an increase in the number of nuclear membrane layers, as described by Morgan *et al.*⁶ for herpes simplex virus, and from which the virus acquires its outer coat. The nuclear membrane is normally double. The most striking finding, however, was the presence of many walled-vacuoles, containing clusters of virus particles, within the nucleus (Fig. 3). In many cases there was distinct evidence of continuity between the double membranes surrounding the vacuoles and nuclear membrane. They were in fact invaginations of the nuclear membrane. Both single- and double-coated virus particles were visible within them. In the case of the double-coated particles the outer coat often showed continuity with inward extensions of the inner membrane of the invagination. The presence of clusters of virus particles seems to stimulate inward movement of the

nuclear membrane resulting in the invaginations. The virus completes its formation by acquiring its outermost coat from the reduplicated nuclear membrane and the virus particles enter the cytoplasm either by rupture of the vacuole at the surface of the nucleus, or more probably by actual extrusion of the whole vacuole. Many of these virus-containing vacuoles are visible in the cytoplasm as also described by Luse and Smith⁷. The method of formation appears to resemble closely that found for herpes simplex virus in HeLa cells by Morgan *et al.*⁶

Cytochemical Changes in Human Amnion Cells infected with Psittacosis Virus

BEDSON *et al.*¹ described the developmental forms of psittacosis virus using conventional staining methods and light microscopy. Subsequent studies by others, who used phase, ultra-violet², and electron³ microscopy, and fluorescein-tagged antibody⁴, helped to describe the complex nature of the replication cycle. In this work, we used Feulgen staining⁵ and fluorescence microscopy with acridine orange dye to demonstrate cytochemical changes in tissue cultures infected with psittacosis virus. Immunocytochemical changes were followed by fluorescent-antibody techniques⁶. Pretreatment of infected cells with ribonuclease was also used in these staining procedures.

When cells stained with acridine orange are viewed with ultra-violet light, the cytoplasm and nucleoli appear rust-red and the nucleoplasm, yellow-green. In this communication, we shall refer to the rust-red colour as ribonucleic acid staining and to the yellow-green as deoxyribonucleic acid staining.

A toxigenic psittacosis virus⁷ in allantoic fluid was inoculated into a line of human amnion⁸ which was propagated on coverslips in Leighton tubes. At time-intervals, cultures were fixed in acid-alcohol, washed in McIlvaine's buffer (pH 3.8), and stained for 4 min. in 0.01 per cent acridine orange prepared in buffer. Cultures were washed and mounted in buffer. They were examined with a Reichert Zetopan microscope and illumination system. At 2-4 hr. after inoculation, deoxyribonucleic acid-staining particles (0.3-0.6 μ) were noted in the cytoplasm. Within the following 24 hr., the initial deoxyribonucleic acid-staining particle was replaced by ribonucleic acid-staining inclusion which was distinct from the surrounding cytoplasm. These inclusions increased in size (1.0-4.0 μ) and in numbers (2-20) until grape-like clusters were formed. During the next 48 hr.,

colour differentiation of the individual inclusions within these clusters occurred in sequence from shades of red to orange to yellow to green. Afterwards, and within the next 48 hr., pin-point (0.2-0.4 μ) deoxyribonucleic acid-staining particles (mature virus) were evident. Re-infection occurred, and the cycle was repeated until the entire cytoplasm was filled with mature inclusions. Infected cells eventually ruptured, thus liberating virus particles into the fluid medium. Infection did not interfere with cell division; mitotic figures were noted throughout the developmental cycle.

Treatment of infected cells with ribonuclease prior to staining with acridine orange effectively removed all ribonucleic acid-staining material from the cytoplasm and nucleoli and from the matrix surrounding the deoxyribonucleic acid-staining virus particles. During all stages of development, the deoxyribonucleic acid-staining material was Feulgen positive. Preparations of the early multicoloured (red-orange) inclusions did not react with a group-related fluorescein-tagged antibody either with or without ribonuclease pretreatment. In contrast, preparations which had reached the yellow-matrix stage were antigenic, but only after prior treatment with ribonuclease. Virus which had reached the mature green-matrix and pin-point deoxyribonucleic acid-staining stages were antigenic with or without ribonuclease pretreatment. That propagation of psittacosis virus in the tissue cultures had occurred was demonstrated by intracerebral inoculations into mice.

By means of acridine orange dye and fluorescence microscopy, the replication-cycle of psittacosis virus in human amnion cells was shown to involve deposition of a ribonucleic acid-containing matrix by the host cell around an initial deoxyribonucleic acid-containing virus particle. Since this matrix could be digested with ribonuclease, it is not considered part of the intact virus and may function as a metabolic pool provided by the host cell.

This work was supported in part by the Hartz Mountain Fund and the James W. McLaughlin Fellowship Fund.

FORTHCOMING EVENTS

(Meetings marked with an asterisk * are open to the public)

Monday, November 28

UNIVERSITY OF LONDON (at the Postgraduate Medical School of London, Ducane Road, London, W.12), at 4 p.m.—Dr. J. S. Robson: "The Renal Excretion of Water in Health and Disease".*

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the London Planetarium, Marylebone Road, London, N.W.1), at 5.30 p.m.—Mr. Leonard Clarke: "Greek Astronomy and its Debt to the Babylonians".

UNIVERSITY OF LONDON (at King's College, Strand, London, W.C.2), at 5.30 p.m.—Prof. A. Bentz (Board of Soil Research, Hanover): "The North-west German Basin".* (First of three Special University Lectures on "The German Oil Fields and their Palaeogeographic Conditions". Further lectures on November 29 and December 1.)

UNIVERSITY OF LONDON (in the Anatomy Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. John O. Corlies (University of Illinois): "Phylogeny and Evolution of the Ciliated Protozoa—Basic Concepts".* (Second of three lectures on "The Evolution of the Protozoa". Further lecture on December 5.)

INSTITUTION OF ELECTRICAL ENGINEERS, EDUCATION DISCUSSION GROUP (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Training for Research" opened by Prof. G. H. Rawcliffe and Dr. G. A. V. Sowter.

ROYAL AERONAUTICAL SOCIETY, AGRICULTURAL AVIATION GROUP (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. J. B. Farrant: "The Farmer's Viewpoint".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (Joint meeting with the DARTFORD AND DISTRICT PHARMACEUTICAL SOCIETY, at the North-West Kent College of Technology, Alskin Road, Dartford, Kent), at 7.30 p.m.—Mr. G. L. Baldit: "Chemical Aids to Crop Protection".

Tuesday, November 29

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. L. E. Glynn: "Auto Antibodies and Diseases of Connective Tissue".* (Twelfth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. A. F. Huxley: "Theories of Muscular Contraction—a Historical Survey" (Inaugural Lecture).*

ROYAL AERONAUTICAL SOCIETY, ROTOCRAFT SECTION (at 4 Hamilton Place, London, W.1), at 6 p.m.—Mr. R. Stanton Jones: "The Design of Ground Effect Machines".

IRON AND STEEL INSTITUTE (at the Hoare Memorial Hall, Church House, Great Smith Street, London, S.W.1), at 6.30 p.m.—Mr. L. Rotherham: "The Contribution of Metallurgy to Electric Power Generation" (Thirteenth Hatfield Memorial Lecture).

Tuesday, November 29—Wednesday, November 30

IRON AND STEEL INSTITUTE (at Church House, Great Smith Street, London, S.W.1)—Autumn General Meeting. Two symposia on: "Fluid Flow in Furnaces and Converters" and "Martensite".

Tuesday, November 29—Friday, December 2

CORROSION AND METAL FINISHING EXHIBITION (in the Empire Hall, Olympia, London).*

Wednesday, November 30

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Anniversary Meeting.

UNIVERSITY OF LONDON (at Bedford College, Inner Circle, Regent's Park, London, N.W.1), at 6.15 p.m.—Prof. W. F. Widdas: "Membrane Permeability and Science".* (Inaugural Lecture).

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS AND COMMUNICATION SECTION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. W. J. Bray: "The Potentialities of Artificial Earth Satellites for Radiocommunication".

ROYAL AERONAUTICAL SOCIETY, MAN-POWERED AIRCRAFT GROUP (at 4 Hamilton Place, London, W.1), at 7 p.m.—Mr. John Barlee: "Some Aspects of Bird Flight".

Wednesday, November 30—Friday, December 2

BRITISH PLASTICS FEDERATION (at Café Royal, Regent Street, London, W.1)—Second International Reinforced Plastics Conference.

IRON AND STEEL INSTITUTE (at the Hoare Memorial Hall, Church House, Great Smith Street, London, S.W.1), at 9.30 a.m. daily—Symposium on "Steels for Reactor Pressure Circuits".

Thursday, December 1

SOCIETY OF CHEMICAL INDUSTRY, CORROSION GROUP (in the Empire Restaurant, Olympia, Kensington, London, W.14), at 2 p.m.—Meeting on "The Influence of Water Movement on Corrosion". Dr. G. Butler: "Ferrous Materials"; Dr. N. V. Newman: "Non-ferrous Metals".

ROYAL INSTITUTE OF NAVAL ARCHITECTS (at 10 Upper Belgrave Street, London, S.W.1), at 4.45 p.m.—Mr. J. H. Conolly: "Strength of Propellers".

INSTITUTE OF REFRIGERATION (at the Institute of Marine Engineers, The Memorial Building, 78 Mark Lane, London, E.C.3), at 5.30 p.m.—Mr. B. J. Perry and Mr. P. D. Lang: "Positive Displacement Rotary Compressors as Applied to Refrigeration".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. W. R. Stevens and Mr. H. M. Ferguson: "Our Civic Lighting: Gloom or Galety" and "A Survey of Street Lighting and its Future".

ROYAL INSTITUTE, LIBRARY CIRCLE (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Mr. Edward Ironmonger: "William Thomas Brande (1788-1866)". (Forgotten Worthies of the Royal Institution, 1.)

UNIVERSITY OF LONDON (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 5.30 p.m.—Dr. B. Lennox: "Nuclear Sexing and Human Chromosomal Anomalies".* (Thirteenth of fifteen lectures on "The Scientific Basis of Medicine" organized by the British Postgraduate Medical Federation.)

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP AND TEXTILE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6.15 p.m.—Meeting on "The Microbiological Breakdown of Cellulose". Dr. J. A. Gascoigne: "The Industrial Significance of Cellulose Breakdown". Mr. P. Russell: "Microbiological Studies in Relation to Moist Groundwood Pulp".

INSTITUTE OF METALS, LONDON LOCAL SECTION (Joint meeting with the LONDON BRANCH of the INSTITUTE OF BRITISH FOUNDRYMEN (at 17 Belgrave Square, London, S.W.1), at 6.30 p.m.—Dr. D. V. Atherton: "The Origin, Detection and Elimination of Gases in Cast Metals".

ROYAL INSTITUTE OF CHEMISTRY, LONDON SECTION (Joint meeting with the BATTERSEA COLLEGE of TECHNOLOGY CHEMICAL SOCIETY, at the Battersea College of Technology, Battersea Park Road, London, S.W.11), at 7 p.m.—Sir Christopher Ingold, F.R.S.: "Nitration and Nitrosation; a Contrast".

UNIVERSITY OF LONDON (at Wye College, Wye, Ashford, Kent), at 8.15 p.m.—Prof. A. C. Schuffelen (Wageningen): "Some Aspects of Research on Soil Fertility".*

Friday, December 2

WORSHIPFUL SOCIETY OF APOTHECARIES OF LONDON, FACULTY OF THE HISTORY OF MEDICINE AND PHARMACY (at Apothecaries' Hall, Black Friars Lane, London, E.C.4), at 5.30 p.m.—Dr. A. H. T. Robb-Smith: "The Growth of Knowledge of Functions of Blood".

INSTITUTION OF ELECTRICAL ENGINEERS, MEDICAL ELECTRONICS DISCUSSION GROUP (at Savoy Place, London, W.C.2), at 6 p.m.—Discussion on "Telemetering Biological Data" opened by Dr. G. H. Byford and Dr. K. G. Williams.

BRITISH INSTITUTION OF RADIO ENGINEERS, COMPUTER GROUP (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 6.30 p.m.—Mr. D. Roberts, Dr. D. S. Campbell and Mr. P. M. Thompson: "Progress in Micro-miniature Circuit Techniques for Digital Computers".

SOCIETY OF CHEMICAL INDUSTRY, FINE CHEMICALS GROUP (at 14 Belgrave Square, London, S.W.1), at 6.30 p.m.—Prof. W. H. Lunnell: "Pharmacy—Art or Science".

ROYAL INSTITUTE (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof. J. Z. Young, F.R.S.: "Control, Constancy and Change in Animal Life".

Saturday, December 3

BRITISH INTERPLANETARY SOCIETY (in the Tudor Room, Caxton Hall, London, S.W.1), at 6 p.m.—Dr. H. C. King: "The History and Future of Telescopes for Astronomical Observations".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (with special qualifications in poultry husbandry) IN THE DEPARTMENT OF AGRICULTURE—The Secretary, The University, Edinburgh (December 5).

SENIOR SCIENTIFIC OFFICER (with an honours degree in physics, and several years relevant experience) at THE DEFENCE STANDARDS LABORATORIES, Department of Supply, Maribyrnong, Victoria, Australia, to take charge of a section engaged in applying X-ray crystallography and electron microscopy to structural problems arising from the chemical, physical and metallurgical work of the D.S.L., including interpretation of results; also applying X-ray diffraction to metallurgical examinations and chemical analysis—The Senior Representative (A.V.82/5), Department of Supply, Australia House, Strand, London, W.C.2 (December 7).

ASSISTANT LECTURER IN PLANT PATHOLOGY IN THE DEPARTMENT OF AGRICULTURAL SCIENCES, School of Agriculture, Sutton Bonington—The Registrar, The University, Nottingham (December 9).

ASSISTANT LECTURER or LECTURER IN APPLIED MATHEMATICS—The Registrar, The University, Sheffield (December 10).

SENIOR PHARMACOLOGIST (well versed in standard classical pharmacology); and a SENIOR PSYCHOLOGIST (well versed in mammalian experimental techniques), to take charge of sections of medical research at the Chemical Defence Experimental Establishment (War Office), Porton, Wilts—The Ministry of Labour, Technical and Scientific Register (K), 26 King Street, London, S.W.1, quoting G.S.97/0A (December 10).

CHAIR OF FLUID MECHANICS WITHIN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, The University, Leeds 2 (December 14).

UNIVERSITY DEMONSTRATOR IN ORGANIC CHEMISTRY—Dr. F. B. Kipping, University Chemical Laboratory, Lensfield Road, Cambridge (December 14).

LECTURER/SENIOR LECTURER IN PSYCHOLOGY at the University of New England, Armidale, New South Wales, Australia—The Secretary, Association of Universities of the British Commonwealth, 36 Gordon Square, London, W.C.1 (Australia and London, December 15).

TEMPORARY RESEARCH ASSOCIATE or RESEARCH FELLOW (suitably qualified medical or science graduate with good experience in enzymology) IN THE BIOCHEMICAL SECTION OF THE DEPARTMENT OF PATHOLOGY, for work in connexion with possible enzyme disturbances in cancer—The Registrar, King's College (University of Durham), Newcastle upon Tyne (December 18).

LECTURER IN ELECTRICAL ENGINEERING—The Registrar, Manchester College of Science and Technology, Manchester 1 (December 19).

CHAIR OF PHYSICS; and CHAIR OF ZOOLOGY in the University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 30).

LECTURER IN BACTERIOLOGY at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 31).

LECTURER or ASSISTANT LECTURER IN PHARMACEUTICS at the University of Malaya, Singapore—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 31).

SENIOR LECTURER IN CHARGE OF THE DEPARTMENT OF PHILOSOPHY, The University College of Sierra Leone (Fourah Bay College)—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (December 31).

ANALYTICAL CHEMIST (with a first- or upper second-class honours degree in inorganic chemistry, or equivalent qualification, and a thorough grounding in this subject, with special reference to inorganic quantitative analysis) in Buchananland, to take charge of the Geological Survey Laboratory, and undertake the analysis of rocks, ores, minerals and ground-water, etc.—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BOD.105/76/05.

ASSISTANT EXPERIMENTAL OFFICERS or EXPERIMENTAL OFFICERS (2) (with a degree in mathematics or statistics, or a degree in agriculture or biology with an interest in experimental work and statistics) IN THE STATISTICS DEPARTMENT, for work on agricultural and biological statistics—The Secretary, Rothamsted Experimental Station, Harpenden, Herts.

CHEMIST (with a good honours degree in chemistry, and at least two years postgraduate research experience, preferably in insecticide analysis), with the PESTICIDES RESEARCH UNIT, Tanganyika, for research into the chemical aspects of the control of tropical pests and to take charge of the chemical laboratory—The Director of Recruitment, Colonial Office, London, S.W.1, quoting BOD.87/8/01.

COMPUTER (with a competent knowledge of, and preferably a degree in, mathematics) IN THE DEPARTMENT OF PHYSICS, to assist research groups by computations using desk calculating machines and an electronic computer—The Professor of Physics, King's College (University of Durham), Newcastle upon Tyne 1.

LECTURERS, ASSISTANT PROFESSORS and ASSOCIATE PROFESSORS IN THE DEPARTMENT OF MATHEMATICS (either at the Edmonton branch or the Calgary branch of the University)—Professor B. S. Keeping, Mathematics Department, University of Alberta, Edmonton, Alberta, Canada.

TECHNICAL EDITOR (preferably with a pass degree or H.N.C., and experience in a related field of work), to be employed on editing, proof-reading, indexing and distribution of scientific reports, technical specifications etc., and to handle related information inquiries—The Senior Recruitment Officer, Atomic Weapons Research Establishment, Aldermaston, Berks, quoting Ref. No. B.2493/34.

THE GREY SEAL AND BRITISH FISHERIES

THE grey seal (*Halichoerus grypus*) appears to have increased considerably in numbers on the coasts of Great Britain during the past forty years. Except from one place, however, there are no comparative figures to show how great the increase may be, or even whether the apparent increase is real. The exception is the Farne Islands where, although the colony of grey seals had been exploited commercially on a small scale for many years during the past century, the population was estimated to number 600-800 in 1928. The National Trust came into possession of the Islands in 1925, and since then the seals have been completely protected. Counts by members of the Natural History Society of Northumberland, Durham and Newcastle upon Tyne have shown that the seal population had increased to 3,000 in 1957, and that it is now about 3,500. It is unfortunate that we have no similar comparative counts of the population in any of the other colonies of grey seals on the coasts of Britain.

For long the grey seal was believed to be a rare British animal, largely because of the vernacular name of *Phoca vitulina*, the common seal. It is difficult for people who are not familiar with the differences between the two native species to identify the animals in the water, for little except part of the head is generally visible. Consequently it has long been customary to assume that any seal seen by chance is a common seal, an assumption that is now known to be unwarranted, for on many parts of the coast the common seal is uncommon, and the grey seal is the species usually seen. It was probably largely this misapprehension that led to the passing of the unnecessary grey seals Protection Act in 1914, a private member's Bill that was slipped through Parliament late at night by a bare quorum at the instigation of a person whose interest in seals seems to have been confined to slaughtering them. This Act, and the second Act of 1932 which protects the grey seal in its breeding season during September 1-December 31, have until recently not been taken very seriously, even by Government departments.

Since 1945 the British seals have attracted the attention of a number of zoologists, who have published numerous papers on their anatomy, physiology, ethology, and general natural history. As a result of these researches, it has become plain that the grey seal is a much commoner animal than was formerly believed; but it is impossible owing to the lack of exact observations in the past to know whether this is due to an increase in the number of seals or in the number of zoologists interested in them. It is equally difficult to form an objective judgment about the complaints of the Scottish salmon netters, who capture salmon in inshore waters and estuaries,

that the numbers of grey seal have increased inordinately. Past records show that salmon netters have always complained of the depredations of seals, and have used various methods to kill them or drive them away, sometimes with conspicuous success.

There is no doubt that seals do inflict considerable damage on salmon nets, and that they destroy or maul some of the salmon captured in them. It is not surprising, therefore, that the net proprietors feel aggrieved that a large population of grey seals, which is known to have increased four- or five-fold in the past thirty years, should enjoy complete protection on the Farne Islands, especially since a number of seals tagged on the Islands have been entangled and drowned in their nets. The netters wish the seal population of the Islands to be drastically reduced, but they are opposed on humanitarian grounds by many people whose material interests are not involved; unfortunately, strong emotions have been aroused on both sides. An attempt at culling some of the young pups in 1959 was unsuccessful for various reasons, and, moreover, it is not certain that control of numbers by killing unweaned pups is the best method. So far as our present knowledge goes, more than 50 per cent of the pups die from natural causes before they reach the age of one year; it therefore seems superfluous to kill pups when so many of them will be dead within twelve months even if no action is taken. Information is not yet available to show whether the killing of adult seals on their breeding grounds is an effective method of control. The breeding colonies are comparatively few, and the concentration of adults on them is high; the breeding grounds therefore appear to be the places where a large reduction of numbers could be attained easily and quickly. But isolated attempts at reducing the seal population by slaughtering some of the animals at one or two colonies do not seem likely to have any permanent effect of significance.

It is by no means certain that all the damage complained of is inflicted by seals from the Farne Islands; nothing is known about the movements of the seals from the much larger colony in Orkney which may be contributing to the damage. It seems improbable, too, that all the seals from these colonies are regularly preying on salmon and damaging the nets. The seal populations are known to total many thousands, yet the seals seen at the fishing stations are counted in dozens or less; if all the population were preying on salmon, the netters' latest returns would be expected to be the worst ever made instead of being among the best. There is some evidence that the damage is inflicted by a minority of the population, and that damage stops when this minority

is removed; but what part of the population is responsible for the damage has not yet been ascertained. There is also evidence that there is some segregation of the population into sex- and age-groups, but much more information is required on this point. The recovery of seals marked as pups has proved that some of them at least travel very long distances in the first few months of their lives, for example from the Farne Islands to Norway, Faroe, and the coasts of Germany, Holland, and Belgium. The movements of older animals have yet to be traced; regular tagging has been carried on for less than ten years, and it is probable that the methods used at first were not efficient, so that the seals lost their tags after a comparatively short time.

It is thus evident that no satisfactory policy about grey seals in relation to fisheries can be settled until the requisite knowledge about their natural history has been obtained. It is for this reason that the Nature Conservancy is at present sponsoring a three-year programme of research on the grey seal, financed partly by the Development Commissioners.

In a recent paper* which should form a useful background to this investigation, Dr. B. B. Rae has attempted to gather together all that has been written about the grey and common seals in relation to fisheries since the passing of the Grey Seal Protection Act in 1914. Unfortunately, Dr. Rae mixes the vague statements of untrained observers with the relatively few proved facts, and tends to reach conclusions some of which start from false premises; he sometimes appears to abandon objectivity by straining to build up a case against the grey seal with statements that are not adequately supported by evidence. There is a *prima facie* case against the grey seal, but the solution of the problems it presents can only be found by patient research and the laying aside of all emotion and bias on both sides. The work is in hand, and if faithfully and diligently prosecuted, there is no doubt that the desired result will be attained.

MIRCESTROL: AN OESTROGEN FROM THE PLANT *PUERARIA MIRIFICA*

By DR. JAMES C. CAIN

National Research Development Corporation, London, W.1

IN 1936, Dr. S. J. Folley, working at the National Institute for Research in Dairying at Shinfield, in England, found that the injection of oestrone or oestradiol benzoate into lactating cows caused prolonged increases in both the fat and the non-fatty solids content of the milk¹. This 'enrichment effect', as it was then called, was later confirmed and further investigated by Folley and his colleagues².

During the early spring of 1948, Dr. H. W. Bennetts, of Perth, Western Australia, discussed with Drs. Bartlett and Folley his findings that reproductive disorders in sheep were due to the ingestion of oestrogenic compounds apparently present in subterranean clover, which at that time was the principal diet of sheep in Western Australia. In view of this finding and the work reported above by Folley and his colleagues, it was decided to initiate work at the National Institute for Research in Dairying on oestrogens in pasture herbage. Dr. Bennetts kindly provided helpful information on the techniques which he had found useful, and advice and help was also sought and obtained from Sir Charles Dodds and his colleagues at the Courtauld Institute of Biochemistry, Middlesex Hospital, London, where also at that time D. H. Curnow, a research worker from Western Australia, was studying herbage oestrogens.

In May 1948 oestrogenic activity was demonstrated in the pasture herbage from a field adjoining the National Institute for Research in Dairying by Bartlett and his colleagues³. This finding posed a host of questions of practical significance for the solution of which it was clear that the resources

available at that time at the Institute and the Courtauld Institute needed to be strengthened on the chemical side. Accordingly, in 1949 Dr. G. S. Pope joined the staff at Shinfield for work on oestrogens in pasture plants; the progress of this work has already been reported⁴.

In the early stages of the work, when attempts were being made to isolate the oestrogens of red clover (aerial portions of the plant), attention was directed to the chemically new and highly potent oestrogen isolated in 1940 by Schoeller, Dohrn and Hohlweg⁵ from the tuberous roots of a leguminous plant in Thailand, investigated from a chemical point of view by Butenandt⁶ (1940). It was evident that this plant source was at least a hundred times as rich in oestrogenic activity as red clover and it became of considerable interest for two reasons. The first was that since both it and red clover are of the family Leguminosae, it seemed likely that the slight activity of red clover was due to a low content of the same new oestrogen as found in the plant in Thailand, and, therefore, that study of the latter might greatly help the work with red clover. (In the event this forecast proved to be wrong, as the activity of red clover was found to be due to the very slightly potent isoflavonoid oestrogens.) The second reason was a natural interest in the new, highly potent oestrogen for its intrinsic value.

At this stage, Mr. D. C. Rivett-Carnac, of the British Embassy, Bangkok, with whom the workers at Shinfield were in touch, directed attention to certain relevant information in some of the Thai scientific journals.

Kerr⁷ in 1932 was the first to direct public attention to the fact that the tuberous roots of the Thai plant, concerned, a woody climber found in the forests of northern Thailand and known locally as *kwao keur*, were considered to be of value as the active constituent of a rejuvenating drug. The information came to him privately from Mr. H. B. Garrett and Dr. E. C. Cort, and the conclusion reached was that the plant was *Butea superba*. Following Kerr's paper, various workers began to collect the roots, and in 1939 Vatna⁸ showed the presence of oestrogen in *kwao keur*, this being confirmed by Schoeller *et al.*⁴. It became clear, however, after detailed botanical investigation in Thailand, that the name *kwao keur* was, in fact, applied to several species of plant having tuberous roots, and that those yielding the new oestrogen belonged to an unnamed species of *Pueraria*, superficially very similar to *Butea superba*. The name *Pueraria mirifica* was given to it by Lakshnakara Kashemsanta, Kasin Suvatabandhu and Airy Shaw⁹.

In 1952 a gift of 6.1 kgm. of dried *Pueraria mirifica* root was received at Shinfield from Mr. Kasin Suvatabandhu, and in 1953 and 1954 batches of 9 kgm. and 4 kgm. were again obtained through the generosity of Mr. Kasin Suvatabandhu and with the assistance of British Council staff in London and Bangkok. Bioassay, using the mouse uterine growth test, of a crude methanol extract of the powdered root confirmed the high oestrogenic activity of the material. The crude methanol extract (6 per cent by weight of dried root) was then submitted to conventional solvent partition procedures giving a product (0.6 per cent by weight of dried root) which contained more than 50 per cent of the oestrogen. Further purification was effected by partition chromatography on kieselguhr columns, and certain fractions from these crystallized in part and yielded a crystalline product (58 mgm. from 6.1 kgm. dried root) when washed with ethyl acetate. Recrystallization from methanol yielded as thin rectangular plates a colourless crystalline product, melting with decomposition at 268° C. (Kofler apparatus). This product appeared to be homogeneous when chromatographed on paper in three different solvent mixtures, in each case showing as a pink spot on reacting with 5 per cent aqueous potassium carbonate and diazotized *p*-aminophenyl 2-diethylaminoethyl sulphone. It appeared, therefore, that the product, of melting point 268° C., was a pure compound, and on testing for oestrogenic activity it was found to be equal to oestradiol-17 β in potency in the mouse uterine growth test, and to have one-quarter of the potency of oestradiol-17 β in the rat vaginal cornification test, in each case oestrogens being administered by subcutaneous injection. The name 'mircestron' was given to the oestrogen; it is doubtless identical to the compound isolated by Schoeller *et al.*⁵.

For further biological and chemical work, and especially for an attack on the structure of mircestron, much larger quantities of the tuberous roots were required. Dr. S. Bartlett was responsible for the arrangements eventually made to collect additional supplies of the root, and he personally supervised the collections on site. The only place where the plant was known to grow was in the forest near Chiangmai in northern Thailand, and it was clear that supplies could only be obtained by means of a collaborative effort with the appropriate local authorities. Those who gave generous help and advice included Prince Lakshnakara Kashemsanta, Mr. Kasin Suvatabandhu, the director and staff of the Maejo Agricultural

Experimental Station at Chiangmai, and Mr. R. J. Hilton, head of the British Council Department in Bangkok.

At this time the interest of the National Research Development Corporation was sought and obtained in this work. The chemical novelty was certain at this stage; the point was whether the structure, when known, might be readily accessible by synthesis from known and abundant substances. The Corporation accordingly undertook to obtain whatever patent protection was possible in the light of prior knowledge and publication and agreed to finance an additional chemist, Dr. D. G. Bounds, at Shinfield, and certain other costs likely to be incurred in the collection of the root, the extraction of mircestron and the determination of its structure.

Two plant-collecting expeditions to Thailand were then undertaken by Dr. Bartlett. The first in 1954, yielding 120 kgm. of dried root, was financed mainly by a grant from Quaker Oats, Ltd., but in part by the National Research Development Corporation, and the second in 1957, which was wholly financed by the latter, yielded 200 kgm.

Mr. Suvatabandhu, a well-informed Thai botanist, knows of only two places in Thailand where quantities of the plant *Pueraria mirifica* grow; one place is at the foot of the mountain Doi Suthep near Chiangmai, and the other is nearly 100 miles farther north at Chiang Dao.

The plant clearly has a local reputation as a rejuvenator. At Chiang Dao, Dr. Bartlett and his Thai colleagues were travelling by car in search of the plant and asked one of the men who were repairing the road if he knew the plant, and he replied, "Yes, we eat it!" The tubers of the plant are almost flavourless and somewhat turnip-like in consistency, and as the Thais are not short of food it may be assumed that *Pueraria mirifica* is eaten for some purpose other than as ordinary food. Further evidence of local interest in the plant may be gleaned from the fact that Mr. Puk Pakkasem, a member of the office staff at the British Consulate at Chiangmai, was able, when requested, to obtain in a few hours thirty local inhabitants who were able to locate the plant in the forest and dig it.

An interesting episode occurred in November 1954, when Dr. Bartlett visited the Siam City Bank in Chiangmai accompanied by Mr. Suvatabandhu. During casual conversation the bank manager, Mr. Kraisi Nimmanahaemino, showed great interest in the fact that they were collecting *kwao* and said his grandfather used to make medicine from the plant and had written a pamphlet about it. Mr. Nimmanahaemino provided a copy of the pamphlet and a pot of 'medicine', which appeared to be a 50:50 mixture of dried *kwao* and honey; it was made in 1953. The pamphlet, in the Thai language, was kindly translated by Mr. Stuart Simmonds, of the School of Oriental and African Studies, University of London, and gave the following information: On the cover was a diagrammatic but accurate sketch of the plant and the description: "Treatise on the Drug made from the Tubers of the Kwao Vine by Luang Anusar Sunthon, Special Commissioner, Chiangmai. Printed at the Upati Pongs Printing House, 3000 copies, May 1931". The main source of information for the pamphlet was a treatise written on palm leaves by 'ancients' and stored in a temple at Pagan, the old capital of Burma. The temple was wrecked by lightning, and the treatise then came to light.

The drug is said to be well known in Burma, where it is called 'paukse', and is stated to rejuvenate old men and women, but should not be taken by young people. One man who took the drug was reputed to have lived to 280 years of age. This local folklore, which appears to ascribe remarkable properties to the *kwao* (or *Pueraria mirifica*) in Burma and Thailand, may well be responsible for the comparative scarcity of the plant. It is not known whether it grows in Burma, but the area of Pagan mentioned in the pamphlet is now said to be an arid desert due to the forest having been cut down in order to build temples.

The pharmaceutical properties of *Pueraria* are considered, in Thailand, to include toxicity, and a careful study of the constituents of the plant has been made in the Chemistry Department of the University of Bangkok. At the Ninth Pacific Science Congress at Bangkok in November 1957, an interesting paper was presented on the "Constituents of the Tuberous Roots of *Pueraria mirifica*" by the Thai workers, T. Nilanidhi, B. Kamthong, K. Isarasona and D. Shienghthong (unpublished work), in addition to a joint one by the Thai and United Kingdom workers, Lakshnakara Kashemsanta, Kasin Suvatabandhu, Bartlett and Pope, on "The Oestrogenic Substance (Miroestrol) from the Tuberous Roots of *Pueraria mirifica*"¹⁰.

The collaboration of the Director of the Royal Botanic Gardens at Kew was sought in an attempt to grow plants of *Pueraria mirifica* there. The first two attempts were unsuccessful, but the third plant, kindly sent from Thailand by Col. E. H. Jacobs-Larkcom, grew and is still growing vigorously. In December 1958 Miss Joy Jacobs-Larkcom collected a number of additional plants in Chiangmai, and these are now also planted in Kew Gardens.

The roots obtained by the expeditions to Thailand were utilized for the following purposes in the studies on miroestrol.

(a) *Improvement of the method of isolation.* The method of isolation has been simplified, and recovery of around 15 mgm. miroestrol per kgm. dried root is now a routine procedure. Paper chromatography, using periodate as reagent, which provides a very sensitive and almost specific colour test for miroestrol, gives efficient analytical control.

(b) *Determination of physical properties.* Miroestrol has been found to crystallize in two forms, a stable hydrated form (stout needles), which after desiccation quickly regains its water of crystallization when exposed to moist air, and a non-hygroscopic, anhydrous form (thin rectangular plates). The latter form has a sharp melting point of 268° C., with some decomposition on melting (Kofler apparatus, rheostat setting 350° C.). Like many steroid hormones, miroestrol has a high dextrorotatory power, $[\alpha]_D^{17} + 301^\circ$ (1.08 gm./100 ml. in ethanol). Its ultra-violet and infra-red absorption curves have also been useful criteria of the purity of the various specimens isolated.

(c) *Determination of oestrogenic potency.* In addition to the properties already noted, miroestrol has been found to have high oestrogenic potency when given orally: approximately three times that of stilboestrol in the immature mouse uterine growth test¹¹ and two-thirds that of stilboestrol in the rat vaginal cornification test. It has also 70 per cent of the activity of oestradiol-17 β when administered by subcutaneous injection, in promoting mammary duct growth in the rat, and is 2.2 times as active as oestrone by a similar test in the mouse¹².

(d) *Preliminary chemical studies.* Elementary analysis and molecular weight determination in Dr. Dorothy Hodgkin's laboratory, University of Oxford, using the X-ray method, gave $C_{18}H_{22}O_4$ as the molecular formula for miroestrol, or less probably $C_{18}H_{24}O_4$. Analysis of the monomethyl ether and monoacetate, in each case the phenolic hydroxyl (see below) having reacted, supported this finding. Other derivatives of miroestrol were then prepared, details of which have been reported elsewhere¹³, and from the ultra-violet and infra-red absorption curves of these and their chemical properties it was concluded that miroestrol is a monohydric phenol possessing one carbonyl and at least two alcoholic hydroxyl groups.

(e) *Preparation of a derivative of miroestrol for X-ray analysis.* The complete elucidation of the structure of miroestrol solely by chemical methods appeared likely to be very difficult with the small amount of material available. It was therefore decided to employ X-ray crystallographic analysis to solve the problem, using three-dimensional methods on a heavy-atom derivative. This work was carried out by Dr. Dorothy Hodgkin and her colleagues at Oxford.

Dr. D. G. Bounds succeeded in making a monobromo-substitution product of miroestrol. At first, bromination of miroestrol with one molecular proportion of bromine gave complex mixtures, but reaction conditions were eventually found which gave a mixture containing only two main products. These were isolated by partition chromatography, and from the elementary analysis and ultra-violet and infra-red absorption curves of one of these compounds, it was concluded that in this compound a single bromine atom had entered the miroestrol molecule replacing a hydrogen atom and that no other chemical changes had taken place. The fact that the monobromo-miroestrol isolated coupled much less readily than did miroestrol with diazotized *p*-aminophenyl 2-diethylaminoethyl sulphone was taken as good evidence that the bromine atom was present as a substituent in the benzene ring of miroestrol.

(f) *X-ray studies.* X-ray crystallographic measurements on monobromomiroestrol were made by Dr. Noel E. Taylor, and the crystal structure was solved in collaboration with Dr. Hodgkin and Dr. J. S. Rollett through a series of three-dimensional electron density calculations carried out on *Deuce* at the National Physical Laboratory. The positions of the atoms found by these calculations are illustrated in Figs. 1 (a) and (b). They lead to the structural formula I, for miroestrol itself:

Full details of this work have been reported elsewhere¹⁴.

Biogenetically, it seems possible to dissect the nucleus into an isoprene unit and a partly reduced isoflavene nucleus. This dissection relates it, on one hand, to the many plant products in which isoprene units are found linked to condensed ring systems (cf.

Fig. 1 (a). Electron density-levels over the peaks in $p8$ in bromomiroestrol. The structure is seen projected along $[010]$. Contours at intervals of approximately 1 el./Å^2 except over the bromine atom, where the intervals are 4 el./Å^2 .

Fig. 1 (b). A view of the molecule of bromomiroestrol, drawn from the atomic positions in $p8$

Robinson¹⁵), and, on the other, to those isoflavones and isoflavones which have been shown to have oestrogenic properties. Miroestrol is not a steroid, and the biological activity is probably a consequence of accidental features of molecular geometry. The actual distance from the 3-OH in miroestrol to the 18-OH is 10.3 Å , which is very near the distance to be expected from models of the 3-OH to the 17-OH of oestradiol. When, however, one compares the disposition of the 17-OH of miroestrol and the 16-OH of oestril relative in each case to the 3-OH, the similarity is not so close; but perhaps it is worth noticing in this connexion that miroestrol is the more potent oestrogen.

(g) *Limited clinical trial.* The trial was carried out by Dr. P. M. F. Bishop and his colleagues at the Chelsea Hospital for Women, London.

Miroestrol has been administered to ten women suffering from amenorrhoea (primary, two cases; secondary, seven cases) or artificial menopause (one case). 5 mgm. daily was given on six occasions and 1 mgm. daily on another six occasions. Marked oestrogen response was noted with both these doses on the vaginal smear, the maximum rise in the cornification index usually occurring during the second or third week after treatment commenced. This peak usually occurred, therefore, after the treatment had been discontinued. Oestrogen withdrawal bleeding failed to take place on six occasions (three with doses of 1 mgm. daily from 5 to 10 days; three with doses of 5 mgm. daily from 2 to 14 days), though withdrawal bleedings had usually occurred in these patients when they had been previously

treated with oestrogens. Withdrawal bleeding did take place on five occasions, however, 7–18 days after the cessation of treatment. The withdrawal interval is much longer, therefore, than with most other oral oestrogens. No toxic effects were complained of on three occasions, the doses being 1 mgm. daily for 7 days, 5 mgm. daily for 8 days and 5 mgm. daily for 14 days, respectively. Toxic effects were rather marked on the remaining nine occasions and consisted of malaise, headache, nausea and in some instances vomiting. They did not seem to be appreciably less severe on the 1-mgm. doses than on the 5-mgm. doses. Work with 0.1-mgm. doses is being undertaken. On four occasions there was enlargement and tenderness of the breasts. These changes were more severe and more frequent on the 5-mgm. doses. On two occasions they were accompanied by marked pigmentation of the nipples, which persisted for some time. In the patient who had received an artificial menopause the hot flushes diminished in frequency and severity for the first week of the 14-day course, but began to return by the fifth day after treatment had been discontinued.

In the light of the limited experience described, it would seem that miroestrol produced marked oestrogenic response in the vaginal smear; is rather slow to act and its effect takes some time to wear off. It does not always induce a withdrawal bleeding, and in the doses so far employed is apt to give rise to rather disagreeable toxic effects.

In view of the undesirable side-effects of miroestrol, it appears unlikely that this substance itself will be suitable for use in medicine in spite of its high level of oestrogenic activity by the oral route. It is possible that modifications of its structure might lead to useful oestrogens, but it is evident that a total synthesis of the whole molecule would be difficult, and not likely to be commercially feasible; also although the miroestrol structure is new, it is, as noted above, related in part to already known oestrogens, and therefore does not display as great a novelty in regard to its structure/action relationship as was at first thought possible; nevertheless, miroestrol presents some features of interest, and further investigations of its biological properties are proceeding.

HIGH-ENERGY PHYSICS

TENTH ROCHESTER CONFERENCE

THE annual international conference on high-energy physics, known more commonly as the 'Rochester Conference', has, over the past decade, produced a sequence of elaborate progress reports on the status of current experimental and theoretical research in one of the most rapidly growing fields of physics. Under the leadership of Prof. Robert E. Marshak, it began in 1950 as an informal seminar at which a handful of specialists considered the implications of the newly discovered π -mesons. When even newer classes of particles were observed in cosmic radiation, and when the great accelerators began to operate, the scope of the conference naturally widened, so as gradually to encompass all the problems that make up the modern science of particle physics. The size of the delegation increased as well, reflecting the growth in the number of physicists engaged in these problems. At the tenth Conference, which was recently held in Rochester, 350 delegates from more than twenty nations gathered in order to assess the results of their most recent research, and to plan the work that lies ahead. The meeting lasted from August 25 until September 1. During the first two days, detailed reports were presented in four simultaneous sessions. These were followed by four plenary sessions during which the earlier discussions were summarized by *rapporteurs*, and three sessions of invited papers on topics of general interest. It is impossible to give a useful account of all these proceedings in abbreviated form, particularly when it is addressed to an audience of non-specialists. I have therefore chosen to review the set of fundamental principles toward the study of which the work at high energies is being directed. I shall then describe some of the more prominent features of the tenth Conference, emphasizing those reports that appear to provide new links in the chain of argument.

Outside gravitation, which seems to play no significant part in nuclear physics, there are three kinds of forces in Nature. The most familiar of them is the electromagnetic interaction, for which the classical theory was developed by Maxwell and Lorentz. Its extension to microscopic phenomena has been achieved in a quantum theory of electrodynamics. The theory describes the interaction in terms of the typical virtual process $e \rightarrow e + \gamma$, where e is any charged particle and γ is a photon. The symbol e also represents the unit of charge, of which all natural charges appear to be exact multiples. The strength of the interaction is measured by the dimensionless universal constant $e^2/\hbar c = 1/137$, $\hbar$ being Planck's constant and c the speed of light in vacuum. The theory has scored many successes, and its essential validity, except possibly at very high energies, is not questioned.

The second kind of force encompasses the 'strong' interactions between particles of certain classes. A quantum field theory of the strong interactions has developed from the original work of Yukawa, and is typified by the virtual process $p \rightarrow n + \pi^+$, where p is a proton, n a neutron, and π^+ a positively charged

pion. The dimensionless coupling constant for the pion-nucleon interaction is $g^2/4\pi\hbar c \simeq 14$, where g has the physical dimension of charge. The fundamental significance of the charge g is no more clearly understood than that of the electric charge e . Furthermore, the coupling constants associated with other strong interactions are presumably different, but all are believed to be of the same order of magnitude. Because of several technical difficulties the theory of strong interactions has proceeded cautiously, guided closely by new experimental discoveries. But certain simplified forms of the theory, developed principally by Chew and his collaborators, have provided semi-quantitative descriptions of many phenomena.

We encounter finally the 'weak' interactions, which are the most mysterious of all the forces. They are typified by the β -decay of a nucleon; for example, $n \rightarrow p + e^- + \bar{\nu}$, where $\bar{\nu}$ is an antineutrino. Weak interactions couple other classes of particles as well. There is no experimentally identified field quantum, analogous to the photon and the pion, associated with the weak interactions. The present description of the phenomena is a development of the original work of Fermi. In his theory, the coupling constant characteristic of a weak interaction is not immediately dimensionless, but it is conventionally written in units that involve the Compton wave-length of the charged pion. Weak couplings so defined have strengths of the order of 10^{-14} , a number to be contrasted with 10^{-3} for the electromagnetic coupling, and with 10 for strong coupling. It appears that weak interactions have at least roughly the same strengths in all their manifestations. This observation has led to the hypothesis of the universality of weak interactions, but a precise formulation of the principle has not yet been made, nor has it been applied quantitatively to experimental data in an unambiguous way. A great advance in our knowledge of weak forces was recently initiated by Lee and Yang. Their suggestion that the interactions need not be invariant to spatial reflexion has been experimentally verified in many different ways, and has led to important clarifications of symmetry principles underlying all physics.

The particles of physics, among which the three types of forces are supposed to act, are separated first into two general groups: the bosons and the fermions. By definition, bosons have spins (intrinsic angular momenta) that are integral multiples of $\hbar$. Fermions have half-integral spins. Bosons are regarded as the quanta of the several kinds of field. Thus photons, with spin unity, are quanta of the electromagnetic field; pions, with zero spin, are quanta of the strong nuclear field. If quanta of the weak field exist, they are also presumably bosons. There is no conservation principle governing the number of bosons that may be created or destroyed in a collision. It is only necessary that energy, momentum, angular momentum, and charge be conserved. The number of fermions, on the other hand, is believed to be subject to strict conservation laws which I shall discuss shortly.

The bosons specifically associated with strong interactions are called 'mesons', and two classes of these particles have so far been observed. In addition to the pions (π) with masses near 0.14 BeV., there are the heavier 'kaons' (K) with masses near 0.50 BeV. (By the 'mass' of a particle I mean, of course, its rest mass. It is most convenient to write rest masses as rest energies in units of MeV. (10^6 electron-volts) or BeV. (10^9 electron-volts).)

There are two sets of fermions. One consists of particles lighter than the mesons, and are called 'leptons'. It includes the neutrino (ν), the electron (e^-), and the muon (μ^-). (Although once called the ' μ -meson' because of its intermediate mass, the muon does not conform to the modern definition of a meson.) The neutrino has zero mass, the electron mass is about 0.5 MeV., and the muon mass is about 106 MeV. The other set of fermions consists of particles heavier than mesons, and is called the set of 'baryons'. It includes the nucleons (N) with masses of about 0.94 BeV.; the Λ -hyperon, with mass 1.12 BeV.; the Σ -hyperons, with masses near 1.19 BeV.; and the Ξ -hyperons, with masses of about 1.31 BeV. The spins of all fermions are almost certainly $1/2$. The baryons interact strongly with each other and with the mesons, and weakly with the leptons.

One may well wonder about the meaning of the term 'elementary particles'. The early periods of modern physics were characterized by searches for ultimate constituents of matter, and there were times when it appeared that the search had ended. The current point of view on this matter is somewhat different. The concept of an elementary particle is now thought to be useful only within a specific context of the contemporary experimental and theoretical situation, taking into account the types of interaction that one is investigating, and the particle properties that one regards as fundamental. In this sense the present list of elementary particles need not be final, even if no new species are discovered.

So far I have mentioned ten classes of particles (γ , ν , e^- , μ^- , π , K , N , Λ , Σ , Ξ). A further subdivision occurs when we take account of the different states of electric charge which most of the mesons and baryons can assume. Thus the π has three charge states (π^+ , π^0 , π^-); the K has two (K^+ , K^0); the N has two (p , n); the Σ has three (Σ^+ , Σ^0 , Σ^-); and the Ξ has two (Ξ^- , Ξ^0). We then have a total of 17 particles. Furthermore, there is believed to be an antiparticle associated with each particle, having properties that are very simply related to those of the particle. This would give a total of 34. However, four of the antiparticles ($\bar{\gamma}$, $\bar{\pi}^+$, $\bar{\pi}^0$, $\bar{\pi}^-$) are experimentally indistinguishable from four of the particles. In this way, we arrive at the 30 unique objects which are under study in high-energy physics.

The multiplicity of charge states bears much formal resemblance to the multiplicity associated with ordinary spin. This observation has led to the idea of an 'isotopic spin vector', I , connected with a given particle or system of particles, and an isotopic spin space in which the vector resides. The z -component of isotopic spin, I_z , selects one of the possible multiplets of the system. For example, the vector I has magnitude unity for the π , with three possible projections on the z -axis representing a triplet (π^+ , π^0 , π^-). The importance of isotopic spin to the subject rests in the observation that I appears to be strictly conserved in strong interactions. The idea has not yet been given significance in the description of leptons.

The mathematical transformation of a particle into its antiparticle is called 'charge conjugation', and is denoted by the operator C . It is equivalent to a reflexion in isotopic spin space. Under the assumption that particle physics conforms to the principles of special relativity, it has been shown that perfect symmetry exists between a particle and its antiparticle. The two have the same mass, spin, lifetime, and modes of decay; they have opposite charge and magnetic moment. This symmetry is beautifully apparent in the electron-positron pair, on which precise experiments have been done. One believes not only that each of the other antiparticles exists (some of the antihyperons have yet to be discovered) but also that it must exhibit the same symmetry. Another powerful theorem based on relativity has been proved by Pauli and Lüders. It asserts that all interactions are invariant under the combined operation CPT , where C is charge conjugation, P is spatial reflexion (the parity operation), and T is time inversion.

All the conservation and invariance principles that are currently accepted in particle physics can now be stated in summary form. Some are taken over from classical physics, but most have only recently come to light as generalizations from new experiments. The list is as follows:

(A) Principles valid in all interactions:

1. Conservation of energy and momentum.
2. Conservation of angular momentum.
3. Conservation of charge.
4. Conservation of baryons (number of baryons minus number of antibaryons).
5. Conservation of leptons (number of leptons minus number of antileptons).
6. Lorentz invariance (CPT theorem; symmetry of particle and antiparticle).
7. Invariance under T (time inversion).

(B) Principles valid in strong and electromagnetic interactions, and violated in weak interactions:

8. Invariance under charge conjugation.
9. Invariance under spatial reflexion.
10. Conservation of I_z .

(C) Principle valid in strong interactions, and violated in electromagnetic and weak interactions:

11. Conservation of I .

In addition to these strict principles, there are several recently formulated selection rules for which much evidence has accumulated. The most completely confirmed of them states that, when mesons or baryons decay into one another, the magnitude of I for the system changes by $\frac{1}{2}$. This rule and some of the conservation principles can be illustrated by considering the modes of decay of the Λ -hyperon. The particle is electrically neutral, has half-integral spin, and has zero isotopic spin. There are several decay modes which are consistent with principles 1-5. Those that involve no more than three decay particles are:

Since the first two modes involve only baryons and mesons, which are strongly coupled to each other, we might expect that the decay would proceed very

rapidly through these channels. But notice that the isotopic spin of the system $N + \pi$ must be a combination of two vectors the magnitudes of which are $\frac{1}{2}$ and 1 respectively. The only isotopic spin states allowed for this system are $I = 1/2$ and $3/2$. Therefore neither I nor I_z can be conserved, and a decay through strong interactions is impossible. The non-conservation of I_z also inhibits the radiative decay (3). We see in addition that, although decay modes of the type $\Lambda \rightarrow N + \bar{K}$ would satisfy conservation of isotopic spin, the mass of the final state exceeds that of the Λ and the mode is impossible if energy is to be conserved. We have thus shown that the particle cannot decay through strong interactions. Furthermore, since the decay does in fact proceed slowly through channels (1) and (2), we know that a weak interaction couples the particles, and we can use the decay rate to obtain an estimate of its strength. (If the Λ could decay through a strong interaction, its life-time would be of the order of 10^{-22} sec. The observed life-time is about 10^{-10} sec.)

Of the remaining modes of decay, (4) and (5) are not forbidden by any known rules, and can be expected to occur as poor competitors of (1) and (2). The remaining modes are forbidden by selection rules that have not been mentioned. Finally, it is to be noted that the $\Delta I = \frac{1}{2}$ rule requires the $N + \pi$ system in the Λ decay to occur only in the $I = \frac{1}{2}$ state. One can deduce from this that the mode $p + \pi^-$ should occur twice as frequently as $n + \pi^0$, a prediction that is well confirmed by experiment.

The fact that Λ cannot decay promptly permits us to regard it as an elementary particle, even though its life-time is short by ordinary standards. The situation is similar for all the unstable elementary particles, which constitute a majority of the list already given. Outside the stable particles (γ , ν , e^- , p), the longest lived is the neutron with a mean life of 10^8 sec., and the shortest lived is probably the Σ^0 -hyperon, the life-time of which, although not yet measured, is expected to be in the neighbourhood of 10^{-18} sec. This example also illustrates the kinds of experiments that must be done in particle physics, and it gives a hint about their difficulty. In order to produce a Λ under controlled conditions, and to observe such a decay mode as $n + \pi^0$, one needs a large accelerator and detectors of considerable refinement. Notice that all the particles are neutral, and so do not produce ionized tracks.

Although the foregoing review constitutes a mere sketch of the high-energy field, it may serve as an adequate background for a short summary of the tenth Rochester Conference. I shall begin with developments concerning the weak interactions. Feynman has looked carefully at the question of universality, with particular attention to the life-time of the muon. Using recent experimental data on the beta decay of oxygen-14, he calculates a muon life-time of 2.251 ± 0.012 μ sec. This is slightly longer than the best measured life-time, the discrepancy of about 2 per cent being considerably larger than the combined error. He concludes that the principle as commonly formulated is not quantitative, and he finds further that high-order corrections to the theory only aggravate the discrepancy. Gell-Mann reported on many recent speculations about this general question. He outlined a more abstract formulation of the universality idea, which might be able to cope with the weak interactions of all particles.

Several new experimental results have lent support to other ideas about weak interactions. Ljubimov (Moscow) described an investigation of the 'helicities' of muons in cosmic radiation. According to current theory, the muons in the decay $\pi^+ \rightarrow \mu^+ + \nu$ should spin in the left-handed sense around their direction of motion. The muons from π^- decay should be right-handed. Experiment confirms both predictions. Chuvilo (Dubna) reported on new observations of the decay modes of K^0 , and showed that they are in agreement with predictions based on the $\Delta I = \frac{1}{2}$ rule. Additional support for the rule, based on asymmetry measurements in pionic decay of Σ and Λ , was reported by Cronin. It might be said here that none of the many experiments recently carried out has cast any doubt on the invariance principles and selection rules outlined above. With regard to strong interactions, I might first mention the current status of one of the oldest problems in nuclear physics. It concerns the force between nucleons. Early research brought out little more than qualitative facts about the strength and range of the force, without clarifying its details. With the advent of the synchrocyclotron, nucleon scattering could be done at energies up to several hundred MeV. It was discovered that such collisions lead to a strong polarization of the scattered beam, and this phenomenon has become an important tool in the most recent measurements of the interaction. At the conference, representatives of the groups at Harwell, Rochester, Harvard, and Dubna reported that almost all their results now fit into a unique and concise empirical scheme, which it is the aim of theorists to explain. With regard to the theory, one can say that the force at relatively large distances (down to about 3×10^{-13} cm.) is now well understood in terms of a single pion exchange potential. The behaviour at shorter distances, where multiple meson exchange is important, has not yet been dealt with quantitatively.

The strong interactions of K , Λ and Σ particles have also been studied intensively in recent work at the higher energies. The reports from Cornell, Saclay, Brookhaven, Berkeley, Dubna and CERN constitute an enormous library of new data on processes of many different kinds. A particularly interesting result was reported by Good (Wisconsin), who has studied the reaction $K^- + p \rightarrow \Lambda + \pi^- + \pi^+$, and has measured the momentum spectra of the pions. He finds structure in the spectra, suggesting the existence of quasi-stationary states of the $\pi - \Lambda$ system.

Bernardini (CERN) reported progress on the design of experiments for the utilization of energetic neutrino beams derived from the great accelerator in Geneva. It is expected on certain theoretical grounds that the cross-sections for neutrino reactions will be much larger at high energies than they are at low energies. For example, Lee and Yang have speculated about the reaction $\nu + N \rightarrow W + \mu + N$, where W is the hypothetical boson associated with weak interactions. The calculated cross-section for this reaction is 10^{-35} cm.² at high energies; the cross-section for the only neutrino reaction carried out to date ($\bar{\nu} + p \rightarrow e^+ + n$) is 10^{-44} cm.² at low energy.

Another important experiment still in the preparatory stage was described by Panofsky. It will investigate colliding beams of electrons, produced in the Stanford linear accelerator and stored in two magnet rings. The equivalent laboratory energy of the collision will be several thousand BeV., and will in

this sense represent by far the highest controlled energy available to physics. It is hoped that the beams can be used to examine the validity of quantum electrodynamics in an energy region which has so far only been accessible in rare cosmic ray events.

Finally, I shall discuss a report by Heisenberg on progress being made in his theoretical group (Munich) toward the development of a general theory of elementary particles. They assume that the most general symmetry principles of the type summarized above are sufficient to specify a differential equation, the eigenvalues of which are connected with properties of the particles. Thus the symmetry principles rather than the particles themselves are regarded as the elementary notions of physics. A prototype of such theories is the relativistic wave equation proposed thirty years ago by Dirac, who was able to give a deductive account of electron spin and to anticipate the discovery of the positron. Several years ago, Heisenberg and Pauli proposed a non-linear spinor equation to which they were led by symmetry considerations. It appears that, since then, some significant steps have been taken toward illuminating the mathematical properties of the equation and deducing some of its physical consequences. There is as yet, however, no strong experimental evidence for or against the theory. Aside entirely from computational difficulties, the theory is open to certain conceptual objections. One of them stems from the

fact that, for the equation to have non-trivial solutions, it must deal with an indefinite metric in Hilbert space. This leads to probability amplitudes of negative norm, for which no interpretation can be given in the usual formulation of quantum mechanics. Heisenberg hopes, however, that all such cases will correspond to virtual states of physical systems, and that negative probabilities may for this reason not be incompatible with the present structure of physics.

It may be clear from this sampling of the conference that the physics of high energies is active on many fronts. It should also be clear that there are fundamental questions still unanswered. Are there still more classes of particles? Are the strict principles of present theory applicable at very small distances and at very high energies? Is there a 'universal' weak interaction, and is there a field quantum associated with it? Are the particles themselves to be regarded as the ultimate entities of physics, or are their properties derivable from a set of simple principles? At any stage in the development of our knowledge there is always a class of questions which seems inaccessible to the methods of physics, but which is nevertheless eventually answered within the context of later developments. It is with a faith strongly supported by this observation that physicists are attacking the provocative questions now before them.

E. M. HAFNER

NEWS and VIEWS

Cloud Physics at the Imperial College of Science and Technology, London : Prof. B. J. Mason

DR. B. J. MASON has been appointed to a newly created chair in cloud physics at the Imperial College of Science and Technology as from October 1960, thus gaining academic recognition for sustained original work in this field over the past decade or so. He joined the Department of Meteorology at the Imperial College of Science and Technology in 1948, following graduation in physics with first-class honours at University College, Nottingham, in 1947 and some research with Dr. G. D. Yarnold on surface tension in the following year. Mason was led to take up research in cloud physics on reaching the Imperial College of Science and Technology, and he soon formed around him an active group of research students concerned mainly with microphysical processes, while his colleague, Dr. F. H. Ludlam, led parallel work on the macrophysics of clouds, to the benefit of the subject as a whole. Cloud microphysics, in Mason's hands, has advanced mainly by his skill in exploiting laboratory techniques and he has designed a number of quite beautiful experiments. Notable among these is the use of the diffusion cloud chamber, in collaboration with Dr. J. Hallett, to determine the forms—needles, plates, prisms, dendrites—in which ice is deposited as a function of temperature and supersaturation. This work has contributed not only to meteorology but, quite notably also, to modern solid-state physics. Mason was awarded the D.Sc. of the University of London in 1956, and was appointed Warren Research Fellow of the Royal Society in 1957. His authoritative text, "The Physics of Clouds", was published in 1957, and he has served on the

Councils of the Royal Meteorological Society and the British Association and on Government research committees. Prof. Mason may now, with extra facilities and his noted enthusiasm, be expected to make an increasing impact on the study of cloud physics in Great Britain.

Physics in Hong-Kong : Prof. W. D. Chesterman

DR. W. D. CHESTERMAN has been appointed to the vacant chair of physics in the University of Hong-Kong. Dr. Chesterman graduated at the University of Bristol in 1934. He then became a student apprentice at the British Thomson-Houston Co. and on completion of his apprenticeship was appointed to the staff of the Company, where he remained until 1939, when he joined the Admiralty. His work in the Admiralty has been mainly in the fields of photographic and optical techniques and in underwater acoustics. He became a Fellow of the Institute of Physics in 1943 and of the Physical Society in 1945. During the past ten years he has gained an international reputation for his work on photographic techniques. He has published a book and a number of papers on high-speed photography, which have been very well received. During 1956–58 he was chairman of the International Committee on High Speed Photography, and in 1958 he was elected a Fellow of the Royal Photographic Society. In 1959 he was awarded the degree of doctor of science by the University of Bristol. The papers put forward for his doctorate included published accounts of his work in the fields of underwater acoustics, illumination optics, high-speed photography and oceanographic research.

Parliamentary Secretary to the Minister for Science

IN moving the second reading of the Ministers of the Crown (Parliamentary Secretaries) Bill in the House of Commons on November 18, the Financial Secretary to the Treasury, Sir Edward Boyle, said that the Bill was designed first and foremost to give the Government greater flexibility in the deployment of Parliamentary Secretaries between Departments, and also, more specifically, it authorized the payment of a salary, not exceeding £2,500 a year, to a Parliamentary Secretary to the Minister for Science. He would be Parliamentary Secretary to the Minister and not to the Ministry, and if the appointment was made questions falling within the responsibility of the Minister would be answered in the House of Commons by the Parliamentary Secretary. Dr. R. Bennett, speaking as chairman of the Parliamentary and Scientific Committee, welcomed the provision as something for which that Committee had been pressing and also paid a generous tribute to the ability of the present Minister for Science. In replying on the debate, Sir Edward Boyle suggested that provision of a Parliamentary Secretary would assist the Minister to pursue his studies in greater detail and that the Parliamentary Secretary would also be able to reply to debates on all the main subjects for which the Minister was responsible. These responsibilities embraced first the Atomic Energy Authority; secondly, the four main executive research councils; and thirdly, those very important advisory bodies, the Advisory Council on Scientific Policy, with its Scientific Man-power Committee, the Overseas Research Council, and the Steering Group for Space Research. If, on the adjournment, members wished to raise the whole question of the work of the Department of Scientific and Industrial Research, or of the advisory bodies, there would be a junior Minister responsible for replying specifically on these subjects.

British Patents and Designs

ON moving the second reading of the Patents and Designs (Renewals, Extensions and Fees) Bill in the House of Lords on November 15, the Earl of Dundee explained that while the Industrial Property Convention of October 1958 made some improvements in existing practice, the only one which needed legislation in Great Britain was the proposed extension from three months to six months in the period of grace allowed for the application for a renewal of a patent or copyright protection for a design. This is done under Clause 1 of the Bill, which also corrects a mistake inadvertently in our own Registered Designs Act but not in the Patents Act of 1949. Clause 2 proposes to repeal the first schedule to the Patents Act, 1949, which specifies certain maximum fees for the registration and renewal of patents but not designs and not trade marks. This schedule to the Act of 1949 is identical with that in the Patents and Designs Act, 1884, and the Earl of Dundee said that it was not proposed to control fees under a statutory instrument as was already done for trade marks or designs, in place of introducing a new schedule. He indicated that if the Bill was passed in its present form the Patent Office proposed to increase the application fee for a patent from £1 to £2, and that for filing the complete specification from £4 to £8. Nearly all the expenses of the Patent Office were in connexion with filing the initial application and the complete specification, and it was proposed to make no increase in the renewal fees, which varied from a

maximum of £5 in the first year to £20 in the sixteenth year, and were mostly still less than the set maxima. While welcoming the first part of the Bill, Lord Silkin urged strongly that the clause relating to revised fees should be withdrawn and introduced as a specific single-clause measure, and this was also supported by Lord Cowley and Lord Ferrier, the former of whom thought the present Clause 2 was contrary to the advice of the Swan Committee in 1947. In his reply, the Earl of Dundee maintained that the procedure proposed by the Government was the most advantageous, and said that the Government had already discussed the matter with interested commercial organizations, none of which had raised any objections to the fixing of fees by statutory instruments rather than by a schedule in an act of Parliament.

International Patent Conventions

THE Catalogue of the Derwent Information Service describes briefly the various publications and services provided (Derwent Patents Abstracts—Catalogue. Pp. ii+38. London: Derwent Information Service, Theobalds Road, W.C.1, 1960. 2s. 6d.). These include reports on British, German, Commonwealth, Belgian and Russian patents in certain specified fields, journals containing abstracts of fine chemicals, plastics, petrochemicals and metallurgical patents, and a series of other patents bulletins dealing with more limited fields. Besides information on patenting procedure in various countries, the catalogue includes an article by M. Hyams on Russian patent law and procedure based on discussions with the Committee for Inventions in Moscow.

Museum of Science and Industry, Birmingham

BIRMINGHAM City Council recently approved a scheme for extending the Museum of Science and Industry in Newhall Street. The new building will replace old property which is structurally unsound and increase the floor area of the Museum to 150,000 sq. ft. The whole scheme is estimated to cost £590,000 and will take not less than six years to complete. The work of rebuilding will be undertaken in three phases; these comprise the erection of a galleried single-storey unit to house, among other large exhibits, the Pacific locomotive *City of Birmingham*; a six-storey administrative, workshop and stores block and another single-storey unit with galleries, in that order. Provision has been made for a lecture room, two cafés and numerous rest rooms. When the scheme is completed public access will be from Fleet Street (which runs at right angles to Newhall Street) by a bridge over the Birmingham-Fazeley Canal.

The site and buildings now occupied by the Museum were once the premises of Elkington and Co., Ltd. (who are well known for the manufacture of silver-plate), until they were taken over by the Committee of the City Museum and Art Gallery in 1950 to house the newly formed Department of Science and Industry. During the past ten years the old factory has been systematically adapted for Museum purposes and opened to the public as each section was completed. The Museum exhibits small arms, veteran, vintage and modern motor-cars and motor-cycles, machine tools, steam engines which are run periodically on live steam, internal combustion engines and scientific instruments covering a wide field. The annual attendances now exceed 400,000.

Science in France

THE second issue of *French Science News*, published by the French Foreign Office and distributed by its Embassy in London, contains considerable information about major French scientific investigations and developments in science and technology. The main articles are concerned with developments in petrology and astronomy while, among pure research items, summaries of work are given on the fundamental theory of corpuscular systems and the concept of the centre of gravity; ultrasonic absorption and dispersion in polyatomic gases; paramagnetic ion relaxation; the production of tritium in thorium by protons of 135 MeV.; the spectra of conversion electrons and *K* and *L* Auger electrons resulting from the disintegration of thulium-170 to yttrium-170; the basic functions of definite symmetry for the wavefunctions of a system of three identical particles; the absorption spectra of selenium and tellurium in ultra-violet light; the equilibrium diagrams of the zircon-oxygen systems of the rare earths; the reactions of the system calcium sulphide-vanadium pentoxide and the preparation and identification of sodium orthonitrates and orthonitrites. Accounts are also given of new developments in apparatus and equipment in various laboratories as well as in engineering. In medicine, details are given of the phosphodiuresis test provoked by parathormone, and the diagnosis of pseudo-hypoparathyroidism in the infant and the risk involved in radiological examinations. Other information includes particulars of new courses at higher education centres, recent books and awards to outstanding men of science. The journal would be considerably improved if the final editing were entrusted to a French-speaking English-born man of science. M. Jean Rostand might then have enjoyed even more his International Kalinga Prize "for scientific vulgarization . . . for the entirety of his work".

Introducing Pedology

MARIAN RAY, of 36 Villiers Avenue, Surbiton, Surrey, has provided an admirable series of filmstrips showing the origin, composition and use of soil. There are five strips in the series, each of which could form the basis of a lesson to scholars taking the Ordinary Level General Certificate of Education examination in biology, or agricultural students at farm institutes. The first, "Rocks and Erosion", describes the main types of rocks and the action of weathering; the second, "Plants and Decay", is concerned with the elements of plant nutrition and their re-circulation. "Soil Profiles" shows how soil formation is influenced by climate, animals and topography; "Soil Composition" describes the physical and chemical bases of soil; while "Soil and Farming" includes such varied topics as soil erosion, pests and diseases, the effects of teaching crop rotation, the effects of fertilizers, farm machinery and different types of British farming. Each strip is in colour and supported by a booklet with concise text and a short bibliography.

U.K. Population Statistics

THE Registrar General's Quarterly Return for the second quarter of 1960 was published in October. The usual periodical returns show a continuation of the relatively high birth-rate, and it is likely that births in 1960 will exceed the figure of 750,000 regis-

tered in 1959 and will be higher than in any year since 1948. Stillbirth and infant mortality-rates continue to decline, and are lower than in any previous corresponding quarter. It is noteworthy that the already low rates have been reduced by 25 per cent during the 1950's. The Return contains an abridged life table for 1957-59, showing an expectation of life at birth of 68.0 years for men and 73.7 for women. The high excess of deaths among males continues, and at ages 55-65 male death-rates were approximately double those of females of the same age. Another table shows the number of years of working life lost per 10,000 population. Among males, cancer, accidents and coronary disease accounted for 40 per cent of the loss; among females, the three most important causes were cancer, bronchitis, and pneumonia and other cardiac diseases (No. 446. Pp. 28. London: H.M. Stationery Office, 1960. 2s. net).

Quarterly Journal of the Royal Astronomical Society

THE *Monthly Notices of the Royal Astronomical Society* has hitherto contained both original papers and material primarily concerned with the affairs of the Society. The increasingly specialized character and growing quantity of papers being published in the *Monthly Notices* has led to the appearance of the new *Quarterly Journal* (1, No. 1 (September 1960). Double issue. Pp. 128. 24s.; Annual subscription 40s.; 6 dollars. Single issues 12s.; 1.80 dollars. (London: Royal Astronomical Society.) 1960). It will contain all that was in *Monthly Notices* other than the original papers. Presidential addresses, George Darwin lectures, reports of observatories, and Council notes will be included, together with articles of the type previously appearing in *Occasional Notes*. The latter publication has been terminated. *Monthly Notices* will in future contain only original research papers. The new journal will appear in future in March, June, September and December each year; but, for technical reasons, two double issues are being published in 1960. It will be sent to all subscribers to *Monthly Notices* and to all Fellows of the Society, and will be on sale to others at £2 per annum. The contents of the first issue, dated September 1960, include an address by Prof. R. O. Redman on the work of the Cambridge Observatories, and articles by Prof. F. Hoyle on the origin of the solar nebula and by Dr. B. E. J. Pagel on the surfaces of stars.

The Transvaal Museum, Pretoria

THE report of the Trustees of the Transvaal Museum, Pretoria, for the year ended March 31, 1960, again refers to the shortage of work, storage and exhibition space which prevents the Museum from exercising its proper function to the community (Pp. 46. Pretoria: Transvaal Museum, 1960). The imposition of an entrance fee of 1s. led to a decrease of about one-third in the total attendance. On the other hand, it has eliminated the disinterested and undesirable visitor who formerly used the Museum as a rest-house and caused much trouble. Two major expeditions to the Gobabeb area of the Namib Desert and Somalia have been organized during the year. The former was made possible by a generous private donation and produced much material and information concerning life under extreme desert conditions.

Fulbright Travel Grants

UNDER the provisions of the Fulbright programme, travel grants are available to citizens of the United Kingdom and dependent territories, to go to the United States for an academic or educational purpose, provided that they have adequate financial support in dollars for the visit, and have been accepted by an American institution of higher learning. Grants cover the cost of direct travel between a candidate's home and the American university or institution. They are available during June 1–August 15, 1961, for which application must be received by March 15, 1961; and August 16, 1961–April 1, 1962, for which applications must be received by June 1, 1961. Application forms and further information can be obtained from the United States Educational Commission in the United Kingdom, 71 South Audley Street, London, W.1.

"McGraw-Hill Encyclopedia of Science and Technology"

THE McGraw-Hill Publishing Co., Ltd., has just published a 15-volume "Encyclopedia of Science and Technology". It is of handy format, each volume consisting of 600–700 double-column pages, and the last volume includes an index to the whole. It is claimed that the work involves 7,200 articles, varying in length from 100 to 1,500 words, contributed by more than 2,000 scientists and technologists from the United States, among whom are many with an international reputation. Continuous revision, the bugbear of any form of encyclopædia, is to be provided by means of "Year Books", beginning in 1962, each consisting of articles on outstanding developments of the preceding year, and shorter notes on important discoveries, new products and applications. The pre-publication price is £61 11s. 6d. (159 dollars); after December 15 the price will be £67 16s. 6d. (175 dollars).

University News:

Birmingham

THE following appointments have been made: *lectureships*, Dr. C. F. Wells (chemistry), Dr. F. Bakhtar (mechanical engineering), Dr. J. L. Jinks (honorary lecturer in the Department of Genetics); *research associateships and fellowships*, G. Lines (medical biochemistry and pharmacology), P. Johnson (medical biochemistry and pharmacology), R. H. Hollier (Tube Investments Senior Research Fellow in the Department of Engineering Production), G. R. Izaak (nuclear physics).

The University has accepted the offer by Joseph Lucas, Ltd., to second to the University each year an American professor, nominated by the University, to hold a Joseph Lucas visiting professorship in the Department of Engineering Production.

Leeds

DR. H. M. N. H. IRVING, of the University of Oxford, has been appointed to the chair of inorganic and structural chemistry, from a date to be arranged.

London

PROF. B. G. NEAL, professor of civil engineering at the University College of Swansea, has been appointed to the University chair of applied science with special reference to engineering tenable at the Imperial College of Science and Technology.

Sheffield

AMONG the appointments to be announced recently are the following: N. Moray, to be lecturer in psycho-

logy; J. E. Enderby, to be lecturer in physics; Dr. J. V. S. Mani, to be I.C.I. Research Fellow in the Department of Fuel Technology and Chemical Engineering.

Sydney

DR. W. N. CHRISTIANSEN has been appointed to the Peter Nicol Russell chair of electrical engineering in succession to Prof. D. Myers. For twelve years prior to his appointment he was engaged in research on radio astronomy in the Commonwealth Scientific and Industrial Research Organization. Dr. L. C. Birch has been appointed to the Challis chair of zoology, which became vacant on the retirement early this year of Prof. P. D. F. Murray. Dr. Birch was appointed to a senior lectureship at the University in 1948 and later became reader in zoology.

Announcements

VISCOUNT AMORY has been appointed chairman of the Medical Research Council, in succession to the Earl of Limerick.

DR. GEORGE W. CORNER, For. Mem. R.S., historian of the Rockefeller Institute, New York, and director emeritus, Department of Embryology of the Carnegie Institution of Washington, has been appointed executive officer of the American Philosophical Society, Philadelphia. He will retain a connexion with the Rockefeller Institute as visiting professor.

THE third international symposium on "Comparative Endocrinology" is being sponsored by the Zoological Society of Japan, and is to be held during June 5–10, 1961, at Oiso. Further information can be obtained from the chairman of the symposium, Dr. Kiyoshi Takewaki, Department of Zoology, University of Tokyo.

AN international pharmacological meeting is being organized under the auspices of the Section of Pharmacology of the International Union of Physiological Sciences, and is to be held in Stockholm during August 22–25, 1961. The general theme of the meeting will be "Mode of Action of Drugs". Further information can be obtained from the First International Pharmacological Meeting, Karolinska Institutet, Stockholm 60, Sweden.

"New Polish Publications" lists new and forthcoming books published in Poland, with annotations in English. The books of scientific interest are classified under the headings: philosophy, psychology, education; economics, social sciences; biology; agriculture, forestry; medicine; mathematics, astronomy, chemistry; geology, geography, geophysics; and techniques. Issues Nos. 1–5, 1960, include some 126 entries under these headings (Agpol Foreign Trade, Advertising and Publishing Agency, Warsaw).

UNDER the title "United Kingdom Postgraduate Awards 1960–62" the Association of Universities of the British Commonwealth has issued a list of such awards tenable at universities in the United Kingdom, and a short list of awards for United Kingdom graduates tenable at universities outside the United Kingdom (Tenth Edition. Pp. ii+136. London: Association of Universities of the British Commonwealth, 1960). There are a subject index to each list and also an index to the named awards. This tenth edition is in a new and larger format, and it is proposed to publish subsequent editions every two years.

HIGH-VOLTAGE ACCELERATORS

AS attendance at international conferences tends to become larger and the programmes more congested, there is an unfortunate tendency for papers to become shorter and more specialized, so that the proceedings of such conferences are largely unintelligible to workers outside a narrow field. In fact, many of the short papers contributed to such meetings present detailed experimental data which arouse little discussion and would be more adequately dealt with by straight publication in journals of the learned societies. An entirely different situation occurs in meetings where the number of papers is limited, and adequate time is available for experts in neighbouring fields to present a more general review of present status, tendencies and difficulties in their respective subjects. With adequate time for discussion, attendance at such meetings can be very profitable not only by allowing informal interchanges between specialists but also by providing others with a feeling for the prevailing current of thinking in each subject, which cannot be obtained by reading the specialist literature.

The advantages of this second type of conference were brought out very clearly at the second Accelerator Conference which was held during October 4-6 at the Krasnapolsky Hotel, Amsterdam. Sponsored by the High Voltage Engineering Co., this meeting brought together more than three hundred scientists from twenty-four countries, either designing or using high-voltage accelerators for a variety of scientific purposes. A total of twenty-two lectures was given, and these brought out strongly the wide range of studies in which such accelerators have become essential. The session on the first day was devoted to applications in nuclear physics; the second to the new tandem accelerators and the types of experiments on which these are now used. Separate sessions on the morning of the third day were devoted to varied topics in neutron physics, isotopes separation, activation analysis, solid state research. The concluding session in the afternoon of the third day outlined contributions in radiobiology, industrial and medical applications and future accelerators for high-power applications.

A major feature of many of the lectures and ensuing informal discussions was the interchange of views on future applications and requirements for high-voltage accelerators. In many nuclear physics problems, highly monochromatic beams of very short duration are needed, whereas for industrial applications lower voltages and less-uniform beams are quite acceptable if the cost per kW.hr. could be reduced. In this connexion the forecasts of accelerator designers are most encouraging. Already the cost has sunk to between 2 and 10 dollars per kilowatt for a 10-kW. machine. With re-design, longer life of components and higher output ratings, we may expect to obtain high-voltage radiation at a total cost of less than 1 dollar per kW.hr., and 5,000 dollars per kW. installed. Although these figures are high compared with electrical energy from 240-V. mains supply, they are very favourable when related to the costs from electrical accelerators at present installed, or the present cost of radioactive isotopes such as cobalt-60. A single

accelerator producing 20 kW. of high-energy radiation has the same energy output as several million curies of caesium-137, which is far greater than the total world production from fission products. Since one kW.hr. of high-energy radiation, if fully absorbed, can give a sterilizing dose of 2.5 megarads to 300 lb. of material, the cost of radiation is no longer an economic handicap in a number of industrial processes. Attempts to discover industrial applications for high-energy radiation have been carried out in a number of industrial laboratories. It is unfortunate that for commercial reasons the more successful applications have not so far received much publicity. The paper contributed by S. H. Pinner and W. H. T. Davison gives an interesting compilation of patents involving radiation which have already been published. These indicate clearly the considerable interest in the polymer field, where a large change can be obtained with a relatively modest radiation dose.

On the nuclear physics side, Prof. P. M. Endt (Utrecht) discussed the use of proton- and gamma-rays in the study of nuclear resonance-levels, and Dr. T. Huus (Copenhagen) summarized work on Coulomb excitation. Prof. L. Katz (Saskatchewan) diverged from his original script to outline his requirement for a research linear accelerator. On the premise that he was only allowed one such equipment for research he laid down the very stringent specification required. The scientists and designers concerned with accelerator design were prepared to meet this technical challenge if the physicists undertake responsibility for finding the necessary money. It was not clear how the many earnest seekers after scientific truth could all congregate at the feet of this valuable, but extremely expensive, oracle.

By using ultra-fast microwave pulse techniques, lifetime measurements of the order of 7×10^{-11} sec. were determined in some odd argon rare earth nuclei by Dr. G. Goldring (Rehovoth). Dr. E. Cotton (Saclay) also gave a short review on nuclear widths and life-times and Dr. A. Schoch (CERN, Geneva) discussed colliding beam techniques.

Electrostatic machines have considerable advantage in the production of continuous beams, and the voltage can be readily adjusted, but there is a limit of roughly 5 MeV. beyond which they cannot operate satisfactorily. This limit had been overcome by the use of tandem generators in which negative ions are accelerated from earth potential to about this voltage, then stripped to give positive ions which continue their path in the same direction. By this means the energy of the beam is doubled. The first of these new tandem generators was installed at Chalk River in February 1959, and Dr. H. Gove (Atomic Energy of Canada, Ltd.) gave details of experiments with this new equipment. In spite of its novel character 80 per cent operational time has been attained with a two-shift programme. The problems studied include proton cross-sections, giant resonance in carbon-14 and silicon-28, and thresholds and yields, departures from Rutherford scattering and narrow resonance structure. Dr. K. W. Allen (Atomic Weapons Research Establishment) also dealt with the advantage of a tandem generator as compared with the

linear accelerator or the betatron for their nuclear work, which involves bombardment with p , d , t and ^3He ions in the energy-range of up to 10–12 MeV. and direct measurement of nuclear life-times of 10^{-11} – 10^{-14} sec.

There is an obvious need for accelerators going to even higher voltages, and Dr. P. Rose (High Voltage Engineering Co.) described plans for three-stage accelerators giving 15 MeV. He also foresaw accelerators furnishing 30-MeV. beams of 10 m.amp. within ten years. Other potential improvements in high-voltage accelerators include millimicrosecond pulsing as compared with the 2- μ sec. pulse at present available (R. Connor, High Voltage Engineering Co.) and more powerful generators using the 'Amplatron' instead of the klystron or magnetron (J. C. Nygard, High-Voltage Engineering Co., and R. F. Post, California).

Ion sources of high efficiency, capable of separating μgm . quantities of rare materials, were described by Prof. J. Kistemaker (Amsterdam), while Prof. R. Fleischmann (Erlangen) discussed polarized ion beams, and Dr. K. Beckurts (Karlsruhe) dealt with pulsed neutron sources and neutron life-time in moderators.

In radiation research, high-voltage beams are valuable in solid-state investigations, as outlined by Dr. P. Baruch (Paris) and have also been used in

chemical analysis, either by gamma or neutron activation (J. W. Otvos, Emeryville). Radiation effects in biological systems, as presented by Dr. W. Huber (Stanford), particularly emphasized aspects of interest to radiation physicists and chemists dealing with radiation damage in much simpler systems.

The time-scale permitted adequate time for private discussions on many specific aspects which could not be raised at the formal sessions. Social activities included a banquet given by the High Voltage Engineering Co., at which Prof. H. B. G. Casimir of the Philips Research Laboratories delivered a witty speech and a reception was held by the Mayor and Aldermen of Amsterdam. This included a Van Gogh exhibition which was very much appreciated. Scientific education is sometimes described as narrow and non-cultural. Perhaps we may hope that students of the humanities who hold this view also relax from their learned meetings by attending exhibitions of classical scientific experiments and reading or discussing recent developments in atomic structure, relativity and quantum theory, the basic concepts of which have an increasingly important influence on the outlook of the modern thinking man.

The full proceedings of the conference will be published at the end of the year in *Nuclear Instruments and Methods*.
A. CHARLESBY

FLOW MEASUREMENT IN CLOSED CONDUITS

FLOW measurement is one of the less-spectacular aspects of fluid dynamics, and perhaps for this reason it has not received the attention it deserves. Nevertheless, flow-metering is as old as the engineering applications of fluid dynamics, since in almost every application it is desirable or important to know the volume or mass flow per unit time passing through the system. For example, the distribution of water in a water grid, the flow of air in an air-conditioning plant, the supply of steam to a turbine, the regulation of the flows in the continuous production of chemical engineering products. The fluids may be gases or liquids and the latter may be corrosive or contain solid suspensions as in sewage or wood pulp. The rate of flow may be small as in a blood vessel or great as in large hydraulic turbine installations and in gas turbines. The nature of the fluid, the size of installation, the speed of flow and the accuracy required, all influence the choice of meter.

Of the more common types of flow-meter, the simplest and most accurate for measurements in liquids consists of a large vessel on a weighbridge into which a given mass of liquid is timed. The National Engineering Laboratory, East Kilbride, possesses a 30-ton weighing tank. Alternatively, a somewhat less accurate but more convenient method is that which uses a vessel designed on the pipette principle, into which a definite volume of liquid is timed. These two methods are generally used as standards against which more compact and convenient flow-meters may be calibrated. The pitot-static pressure head has been widely investigated, and used by aerodynamicists for measuring the velocity at a point in air flows, and is regarded by them as a fundamental instrument. By traversing the instrument across a

duct the velocity distribution and hence the flux can be found. Small rotating vanes coupled to counting devices and known as current meters can also be used to find the velocity at a point after calibration, and hence the volume flow can be found by integration. A great many meters in practical use utilize a pressure difference brought about by a change of cross-sectional area of the duct. In nozzles and venturi meters this change of area is smooth and gradual, and such meters introduce little loss into the duct system, but they are fairly sensitive to upstream disturbances. In the orifice-plate type of meter the change of section is sudden, and a large resistance is offered to the flow, which gives rise to a large pressure difference. Another method, used in hydraulic power installations, involves the steady injection of a solution of salt at a known rate. Samples are then taken downstream where the mixing is complete, and from the dilution the mass flow can be found. A variant of this makes use of radioactive isotopes. Some methods attempt to measure the mass or volume flow directly without introducing any obstruction into the duct. An interesting example is the magnetic flow-meter, in which a magnetic flux is set up at right angles to the flow of a conducting liquid, and a current flows between two electrodes in the pipe wall which can be related to the volume rate-of-flow. The meter is of particular value in water-borne sludges. Another example of considerable practical importance is the Gibson method. In this the fairly rapid closure of a valve, or of the inlet guide vanes of a hydraulic turbine, causes a pressure variation with time between two stations in the pipe line. The integral of this over the time of closure is related closely to the

destruction of momentum and so to the mass-rate of flow.

During September 27-30 a symposium on "Flow Measurement in Closed Conduits" was held in the new James Watt building of the National Engineering Laboratory. It was the first of a series which are to be held there, and so far as can be discovered, it was the first symposium devoted solely to flow measurement which has been held anywhere. Some 150 delegates were present; about 50 coming from countries of Western Europe, the United States and the Dominions and the remainder from British manufacturers, industrial users, official establishments and universities. The symposium occupied four days, and on the last evening the delegates attended a dinner at the Central Hotel, Glasgow, given by the director, Dr. D. G. Sopwith, to the authors of the papers. On the last afternoon, the delegates were invited to look around the various laboratories of the National Engineering Laboratory.

Dr. Sopwith was chairman at the opening session when the first item was the presentation of a film made by the National Engineering Laboratory at the Kinlochleven power-station, showing the comparative testing of a number of flow-meters. This was followed by the 'opening address' given by Vice-Admiral Sir Frank Mason, chairman of the Steering Committee of the National Engineering Laboratory. The remaining six sessions were devoted to the discussion of twenty-nine papers.

Session A was concerned with current meters and pitot tubes, and included contributions from the United States (1), Italy (1), France (2), and the United Kingdom (2). Session B discussed orifice plates, with papers from the United States (1), United Kingdom (2), France (1). Venturi-meters formed the subject of Session C, with papers from the United States (1), Belgium (2), and the United Kingdom (1). Session D dealt with the various other pressure difference devices, with contributions from the United Kingdom (2), West Germany (1), Austria (1), and the United States (1). Session E was devoted to salt dilution and salt velocity methods, with papers from the United States (1), France (1) and the United Kingdom (2). Session F discussed the Gibson method, with papers from Norway (1), and the United Kingdom (1). Session G was concerned with special methods, and papers were presented from the United Kingdom (3), West Germany and Holland (1). All papers were in English and the

discussions were in English, and though translator services were available these were required but once. The papers and the discussions are to be published as a bound volume. The excellent organization of the symposium by the deputy director, Dr. Hutton, and by Dr. Winternitz and his staff of the Fluid Mechanics Division of the National Engineering Laboratory, ensured that the maximum time was available for the discussion of the papers. The discussions were frank and helpful and were enlivened by certain overseas visitors with a nice sense of humour.

The theme of most of the papers and the discussions was the question of accuracy or constancy of the calibration coefficient. This is a very important feature of any flow-meter, and it was clear from the papers that considerable effort is being made to improve existing flow-meters in this respect. Present-day standards of accuracy for most flow-meters fall far short of those for physical measurements; for example, a reliable accuracy of 1 per cent must be regarded as rare. There are good reasons for this, since most flow-meters are affected by scale effects (Reynolds number), effects arising from upstream installations, such as bends and changes of section, turbulence and compressibility (in the case of gases), by erosion, corrosion and solid deposits which can cause deterioration with time. This question of accuracy is, in many cases, of great practical importance. In chemical engineering, accurate metering and regulation of the flow of the various products in continuous-flow processes is desirable on both technical and economic grounds. The manufacturers of pumps and turbines are frequently called on (in the case of large units) to meet very stringent performance specifications, which involve quantity flow, and it is essential that the manufacturer and the user should agree on the flow-metering accuracy. Since many countries export turbo-machinery, flow-metering has an international importance. One of the important results achieved by the symposium was not only the bringing together of the manufacturers, users and research workers, but also the achieving of this on an international level, so that a wide variety of experience was pooled and important personal contacts were made.

In conclusion, therefore, it can be stated that the symposium was timely and a great success, due mainly to the excellent arrangements made by the Fluid Mechanics Division of the National Engineering Laboratory.

J. H. PEARSON

PROGRESS IN CALORIMETRY

THE fifteenth annual Calorimetry Conference was held at Gatlinburg, Tennessee, during September 7-10, with Oak Ridge National Laboratory acting as host and Dr. J. P. McCullough (Petroleum Thermodynamics Laboratory, Bureau of Mines) serving as chairman. In the pleasant surroundings of the Great Smoky Mountains, 106 calorimetrists from the United States, Canada and Europe heard and discussed thirty-one technical papers on recent work on many phases of calorimetry and engaged in informal discussions of calorimetric problems. Among the topics discussed were calorimetry at temperatures

as low as 0.1° K. and as high as 2,800° K., precision reaction and bomb calorimetry, solution calorimetry, applications of calorimetry to solid-state problems, application of calorimetry to radiation dosimetry, improvements in temperature measuring devices, and data processing by digital computers. At the Conference banquet, Dr. A. M. Weinberg, director of Oak Ridge National Laboratory, shared his experiences and observations on a recent trip to the U.S.S.R. with the chairman of the U.S. Atomic Energy Commission, illustrating his talk with a number of interesting slides. Dr. D. W. Osborne

(Argonne National Laboratory) was programme chairman, and Dr. R. H. Busey (Oak Ridge National Laboratory) was local arrangements chairman.

The Hugh M. Huffman Memorial Lecture, established in memory of the founder of the Calorimetry Conference, was given by Prof. J. W. Stout (University of Chicago) on the subject "Magnetic Entropy in Ionic Crystals". Prof. Stout gave a stimulating lecture on the magnetic contribution to the entropy of ionic salts of the transition metals, discussing the theoretical considerations and the results obtained from low-temperature heat-capacity measurements and from experiments on magnetic susceptibility, paramagnetic resonance, and optical absorption.

Several papers were devoted to a perennial concern of the Conference: the improvement of temperature-measuring devices. Further tests of the germanium resistance thermometers developed at the Bell Telephone Laboratories were described, with H. Plump reporting on "Low Temperature Thermometry at the National Bureau of Standards" in the range 2–20° K., and C. van Rijn, H. van Dijk and M. Durieux (Kamerlingh Onnes Laboratorium, Leyden) reporting on "Calibration of a Germanium Resistance Thermometer at Liquid Helium and Liquid Hydrogen Temperatures". These devices show such encouraging promise for precision temperature measurements from 1° to 20° K. that a committee has been seeking a manufacturer of additional germanium thermometers for further testing. P. Lindenfeld (Rutgers University), chairman of the committee, reported that the Minneapolis-Honeywell Regulator Co. has become interested, and G. Halverson of that Company showed several pilot models.

Results in a quite different temperature region were presented by J. P. Evans (National Bureau of Standards), who described the development of platinum resistance thermometers for the International Temperature Scale from 630.5° to 1,063° C. It is expected that the use of such thermometers will simplify and smooth the scale, as well as provide greater precision and reproducibility than is possible with present thermometric instruments. Also, the use of thermistors for measuring small changes of temperature in solution calorimetry was described in several papers. A notable example was the paper by G. R. Argue, E. E. Mercer, and J. W. Cobble (Purdue University) on "An Ultrasensitive Thermistor Microcalorimeter" for the determination of the heats of solution of the heavy elements with quantities as small as 5 or 10 µgm.

Several authors reported on applications of calorimetric techniques to solid-state physics. J. E.

Kunzler (Bell Telephone Laboratories), for example, discussed methods for the observation of very small amounts of energy—between 10^{-3} and 10^2 ergs—and the application of these techniques to investigations of magneto-thermal oscillations of single crystals of bismuth and the adiabatic demagnetization and heat capacity of ferrimagnets.

A subject of great interest to calorimetrists measuring or analysing heat capacities was presented by B. N. Brockhouse (Atomic Energy of Canada, Ltd.) in an invited paper on "Dispersion Curves and Frequency Distributions of Lattice Vibrations from Neutron Scattering". A novel cryostat for low-temperature calorimetry from 4° to 80° K. was described by V. Mathot (Free University of Brussels), along with experimental results on the heat of mixing of hydrogen and deuterium liquids. Another interesting new type of cryostat, a helium-3 cryostat with a lead wire thermal switch for cooling the calorimeter to 0.3° K., was depicted by D. L. Martin (National Research Council of Canada).

The Conference is deeply interested in the adequate presentation of calorimetric and thermodynamic data. For this reason the fifteenth Calorimetry Conference considered carefully and adopted a "Resolution on Publication of Calorimetric and Thermodynamic Data" which is intended to be a guide for authors, editors and referees of calorimetric papers. This resolution is a revision of one adopted in 1953 that has been valuable to authors and editors alike.

Plans were announced for the next conference, which will be an International Calorimetry Conference and will be held at Ottawa during August 14–17, 1961. The meeting will be jointly sponsored by the Calorimetry Conference and by the Subcommittee on Experimental Thermochemistry of the Commission on Chemical Thermodynamics of the International Union of Pure and Applied Chemistry. The host organization will be the National Research Council of Canada.

At the annual election the following officers were elected: *chairman*, Dr. D. W. Osborne (Argonne National Laboratory); *chairman-elect*, Dr. J. E. Kunzler (Bell Telephone Laboratories); *secretary-treasurer*, 1960–63, Dr. G. T. Furukawa (National Bureau of Standards); *directors*, 1960–62, Dr. G. T. Armstrong (National Bureau of Standards) and Dr. J. K. Logan (Naval Research Laboratory). Other directors of the Conference are: Dr. J. P. McCullough, Prof. David White (Ohio State University), Prof. N. E. Phillips (University of California, Berkeley), and Prof. J. M. Sturtevant (Yale University).

THE INTERNATIONAL ASSOCIATION OF VOLCANOLOGY

THE International Association of Volcanology, under the aegis of the International Union of Geodesy and Geophysics, met in Helsinki during July 25–August 6, with Prof. A. Rittmann, who is a Swiss citizen, as president.

Mr. G. R. Laclavère, in his capacity as interim secretary in place of Prof. F. Signore, who died on December 2, 1959, reported that since the last general assembly in Toronto in 1957, five parts of the *Bulletin Volcanologique* and six parts of the Catalogue

of Active Volcanoes (Africa, Melanesia, Central America, Kurile Islands, Kamchatka and the U.S.A.) had been published, and in September 1958 fifty-four volcanologists, from twelve countries, had met in Paris for a symposium.

In Helsinki, under the presidency of Prof. A. Rittmann, and with the assistance of the local secretary, Prof. Th. G. Sahama, the work of the Association was arranged in four sections: (1) active volcanoes (six papers and six reports); (2) physics of volcanoes

(four papers, also five papers combined with section 1); (3) physical chemistry and chemistry of magmas, volcanic waters and volcanic gases (eighteen papers); (4) paleovolcanology and plutonism (fourteen papers).

Altogether fifty-five contributions were submitted to the Association from fourteen countries, distributed as follows: U.S.S.R. 15, United States 8, France 6, Japan 6, Australia 4, Great Britain 4, Belgium, Italy, Portugal and Switzerland 2 each, India, Mexico, Netherlands and Norway 1 each. Of these contributions forty-three were read and discussed. In addition, two papers on lunar volcanoes were submitted. Prof. A. Rittmann's presidential address dealt with the geochemistry of basalts and the mechanism of their eruption. The national reports on recent volcanic activity were contributed by Australia, India, Japan, Mexico, United States, U.S.S.R.

Several joint symposia also were held on the subjects of: (1) isotope geology and experimental petrology; (2) the age of minerals, Pre-Cambrian rocks and meteorites; (3) island arcs and the ocean floor.

Two discussions were held under the combined auspices of the International Association of Volcanology, the International Association of Seismology and the Geochemical Commission of the International Union of Pure and Applied Chemistry, on the question of the position of geochemistry within the International Union of Geodesy and Geophysics and other international scientific unions. As a result, a request was made to the Council of the International Union of Geodesy and Geophysics for the establishment of an *ad hoc* committee on 'Geochemical Problems'. The function of the committee would be: (1) to arrange meetings in the field of geochemistry under the auspices of the committee, or under the joint sponsorship of the committee and other sections of the Union; (2) to promote the furtherance of geochemistry by investigating the possibility of a relationship between the International Union of Geodesy and Geophysics, the International Union of Pure and Applied Chemistry, and any

other international body in the field of geology which may be formed.

During the Assembly two volcanological colour films of outstanding interest were shown, illustrating a spectacular basaltic eruption in Hawaii, and also the remarkable achievements of the Belgian expedition which recently studied the lake of molten lava far down in the crater of the Congolese volcano Nyiragongo.

The president, Prof. A. Rittmann (Catania University), announced a decision, taken jointly by the Department of Volcanology of Catania University in Sicily and the Belgian National Centre of Volcanology, to explore the possibility of creating an International Institution for Volcanological Research in Catania, close to Etna.

The Association expressed approval of the Executive Committee's plan to hold two symposia before the next General Assembly, the first to be on the formation of ignimbrites, hyaloclastites and related deposits, and to be held in Catania during October 1961, and the second on the prediction of time and place of volcanic eruptions and the relationship between magmas and the nature of volcanic eruptions, to be held in Tokyo (Japan) during May-June 1962.

The Association also approved the proposal that a *Bulletin of Volcanic Eruptions* should be instituted. Such a publication, recording briefly current volcanic phenomena, should appear up to four times a year, and it should be distributed to National Sub-Committees for Volcanology and to certain individuals. It is anticipated that the Volcanological Society of Japan will agree to undertake and finance publication and distribution.

Office bearers for the triennium 1960-63 were elected as follows: *president*, Prof. A. Rittmann (Switzerland); *vice-presidents*, Prof. V. I. Vlodavetz (U.S.S.R.) and Mr. Gordon A. Macdonald (United States); *secretary*, Prof. F. Penta (Italy); *chairman of Section I*, Dr. M. Neumann van Padang (Netherlands); *chairman of Section II*, Dr. G. S. Gorshkov (U.S.S.R.); *chairman of Section III*, Prof. H. Kuno (Japan); *chairman of Section IV*, Prof. B. Göze (France).

UNIVERSITY DEVELOPMENT IN BRITAIN

THE statement issued by the Association of University Teachers on the problems of university development is one which should be carefully studied by all who are concerned with policy-making in this vitally important field*.

The Association is concerned about the arbitrary way the University Grants Committee has recommended that university expansion should cater for two scientists against one entrant for all other faculties, including medicine and agriculture, and asks that this matter be reconsidered.

Agreeing with the University Grants Committee's estimate that the number of university students in Britain by 1970 should be about 170,000, the Association believes that present standards of entrance to the university should be maintained, and is of the

opinion that there should be sufficient applicants of quality to maintain that standard for at least 170,000 places, and that this figure may have to be exceeded.

To cater for the additional 70,000 students for whom places will have to be found in the next ten years, a major operation will be required. This can be done by increasing the size of existing universities or by founding new ones. Recognizing all the attendant dangers to institutions which grow too large, the Association recommends that at least six new universities should be started during the next two years.

The arguments for new universities are strong. Their building cost can be shown to be no greater than that of expanding existing universities, while the difficulty and cost of acquiring land must be less. The contribution that they can make in terms of variations in teaching methods and added range of research is considerable. There should be a deliberate

* "Some Problems of University Development". Pp. 7. (London: Association of University Teachers, 21 Dawson Place, W.2, 1960.) 1s. 6d.

policy of preserving the pattern of university life to be found in the smaller and medium-sized universities; this cannot be achieved without creating new universities.

It has been argued that because new universities have to be created and built, no appreciable contribution can result during the next decade. The Association believes that this depends on the urgency of the approach to the problem.

The Association makes a clear recommendation that new universities should be planned from the beginning for what is regarded as their likely size. Thus, a university planned for 3,000–3,500 should start with the appropriate building plans, which may be phased but should not require subsequent revision. A maximum of 4,500 should leave ample scope for later expansion to accommodate whatever specialism an individual university may adopt. The new campus should be built with all the buildings going up simultaneously. The intake in each of the first three years might be 750–800 undergraduates, building up in the three following years to 900, leaving the balance for postgraduate places. To do this requires an approach to planning and construction comparable with large industrial organizations.

The planning of the university itself as a centre of research and learning should be approached in an equally dynamic fashion. There is no time for a consultative committee to work out the charter for each university and its range of subjects. The experience gained in the creation of universities in

North Staffordshire and at Brighton should be drawn on immediately, and a draft charter should be devised for each university which would be expressed in terms allowing a flexible approach by the universities concerned, and each such charter should be revised at the end of ten years.

To meet the urgency of the situation, it is suggested that the vice-chancellor, the deans of faculties, the librarian and the senior administrative officers be appointed immediately the university is created, the heads of departments should be appointed eighteen months before the first students are admitted, and other staff should be recruited during the ensuing period. An approach of this nature would enable a university to open its doors four years after the decision to create it, and seven years from the decision being taken one could expect to find 2,500 students in residence, and 3,000 ten years later. If this procedure were followed for six or more new universities, there would be a solution to the likely balance of demand before the end of the 1960's.

The Association believes that the new universities should be located in towns with not less than 50,000–100,000 population. They should be broadly based, and not of the character of either a liberal arts college or a two-faculty university. There should be opportunities for the individual development of rarer faculties. In each there should be found arts, social science, science and applied science. The applied sciences should be linked with the region in which the university is established.

GENERAL RELATIVITY AND LORENTZ-INVARIANT THEORIES OF GRAVITATIONS

By DR. G. J. WHITROW and DR. G. E. MORDUCH

Department of Mathematics, Imperial College of Science and Technology, London

DESPITE the initial successes of Einstein's general theory of relativity, attempts to produce a satisfactory Lorentz-invariant theory of gravitation have persisted until the present day. The three well-known Einstein tests are all obtained from the Schwarzschild metric, that is the general relativity solution of the one-body problem. There has been no direct confirmation of the field equations of the theory; but in time it should prove possible to test the results of the two-body problem in the theory as far as terms of order $1/c^2$.

Although more cogent in its aesthetic and general intellectual appeal than rival theories, general relativity is not unique in the results it predicts for the motion of perihelion, deflexion of light-rays and gravitational red-shift in the one-body problem. The same results are obtained in some Lorentz-invariant theories of gravitation. No general analysis has previously been made of these theories, nor have the results predicted by them been systematically compared with the corresponding formulae derived from general relativity. We have therefore recently made a thorough review of Lorentz-invariant theories, and the details of our analysis will be published later. It is the object of the present communication to present our principal conclusions.

We have considered seven possible tests in all: the three well-known tests obtained for the one-body problem; the secular acceleration of the centre of mass and the advance of periastron in the two-body problem; and the two additional effects introduced into the one-body problem when the axial rotation of the central body is taken into account. The formulae for these effects have all been obtained previously in general relativity, at least to order $1/c^2$. Corresponding formulae for some of these effects have previously been obtained in some Lorentz-invariant theories. We have derived the required formulae for all the theories that we have considered.

Before setting out the comparative tables of results, we must explain our method of classifying Lorentz-invariant theories, which includes some not previously discussed. Attention is, of course, restricted to theories which satisfy the condition that they reduce to the Newtonian form when c is replaced by infinity. (The basic reason for seeking to replace the Newtonian theory of gravitation is that the theory is applicable only when c can be taken as effectively infinite.) First we consider in turn theories in which the gravitational potential is (i) a scalar, (ii) a vector and (iii) a second-order tensor.

Scalar Theories

Under this heading, we consider Nordström's theory¹ and a generalization which includes as special cases theories due to D. E. Littlewood² and O. Bergmann³. In this generalization Laplace's operator in Poisson's equation for the potential φ is replaced by D'Alembert's operator, and the equations of motion are obtained from the variational principle:

$$\delta \int \exp\{-f(\varphi/c^2)\} ds = 0$$

where ds^2 is the Minkowski metric, and:

$$f(x) = x + qx^2 + \dots$$

Nordström's own theory is given by $f(x) = x$, whereas Littlewood's and Bergmann's theories, although derived from different initial assumptions, are both given by $f(x) = -\log(1 - x)$.

A different type of scalar theory, associated with a uniformly expanding world-model, was devised by E. A. Milne⁴ and considered further by G. L. Camm⁵, G. J. Whitrow⁶, A. G. Walker⁷ and W. S. Krogdahl⁸. In this theory the mutual potential energy of a particle of mass m_1 at x_1^a ($a = 1, 2, 3$) at time t_1 and a particle of mass m_2 at x_2^a at time t_2 is given by:

$$- \frac{m_1 m_2 c^3}{M_0} \frac{X_{12}}{(X_{11}^2 - X_{11} X_{22})^{1/2}}$$

where $X_{rs} = t_r t_s - x_r^a x_s^a / c^2$, $M_0 = c^3 t / G$, t being the present epoch and G the constant of gravitation. The condition $X_{11} = X_{22}$ is imposed.

In all these theories it is assumed that the velocity of light c is a constant. We have, in addition, considered two types of scalar theory involving a variable velocity of light (function of the field):

(i) derived from the variational principle:

$$\delta \int ds = 0$$

where $ds^2 = c^2 dt^2 - dx^a dx^a$. (This leads to the same equations of motion as were obtained in 1912 by Einstein⁹.)

(ii) Derived from the variational principle:

$$\delta \int \exp(-\psi/c^2) ds = 0$$

where $ds^2 = dt^2 - dx^a dx^a / c^2$, ψ satisfies the modified Poisson equation (with D'Alembert's operator), and $c^2 + 2\psi = \text{constant}$. (This is of Nordström's form, except that c is now a function of the field.)

Vector Theories

Under this heading, we have examined first a generalized Maxwell type of theory not previously considered in which the vector potential φ^a ($a = 0, 1, 2, 3$) satisfies the equations:

$$\square \varphi^a = 4\pi \frac{G\rho}{c^2} \frac{dx^a}{ds}$$

where $\square$ denotes D'Alembert's operator, ρ is the density, and the equations of motion are of the form:

$$\frac{d^2 x^a}{ds^2} = g^{ab} \left(\frac{\partial \varphi_b}{\partial x^\gamma} - \frac{\partial \varphi_\gamma}{\partial x^b} \right) \frac{dx^\gamma}{ds} + p \frac{d\varphi_a}{ds} \left(g^{ab} - \frac{dx^a dx^b}{ds ds} \right)$$

where g^{ab} is the contravariant Minkowski tensor and p is a constant. If $p = 0$, these equations of motion

are of Maxwell type and are derivable from the variational principle:

$$\delta \int (ds - \varphi_a dx^a) = 0$$

We have also examined a wide class of vector potential theories with several disposable parameters recently introduced by P. Kustaanheimo¹⁰. He postulates equations of motion of the form:

$$\frac{d^2 x^a}{ds^2} = \frac{\partial \varphi^\eta}{\partial x^a} B_{\beta\gamma\eta}^{as}(\varphi^\delta) \frac{dx^\beta}{ds} \frac{dx^\gamma}{ds}$$

where φ^δ satisfies the first equation in this section and $B_{\beta\gamma\eta}^a$ are general tensor functions of φ^δ .

Tensor Theories

Under this heading (which, strictly speaking, includes general relativity) we consider Birkhoff's theory¹¹, Whitehead's theory¹² and the generalization of the latter due to A. Schild¹³.

In Birkhoff's theory the distribution of matter is represented by the energy-momentum tensor:

$$T^{ab} = \rho \frac{dx^a}{ds} \frac{dx^b}{ds} - \frac{p}{c^2} g^{ab}$$

where ρ is the density, p the pressure and g^{ab} the Minkowski tensor. The condition $p = \frac{1}{2}\rho c^2$ was imposed by Birkhoff in order that the effects of small disturbances be propagated with velocity c . The gravitational tensor potentials h^{ab} are defined as the solutions of:

$$\square h^{ab} = (8\pi G/c^2) T^{ab}$$

subject to the boundary conditions that all h^{ab} are zero at points infinitely distant from gravitating matter. Birkhoff assumed that the equations of motion of a test-particle are given by:

$$\frac{\partial T^{ab}}{\partial x^\beta} = f^a$$

where f^a is the body-force per unit volume. He also postulated that f^a is perpendicular to dx^a/ds , is linear in the first derivatives of the tensor potentials, quadratic in dx^a/ds and proportional to the proper density of the particle. The equations of motion then reduce to the form:

$$\frac{d^2 x^a}{ds^2} = g^{ab} \left(\frac{\partial h_{b\gamma}}{\partial x^\delta} - \frac{\partial h_{\gamma\delta}}{\partial x^b} \right) \frac{dx^\gamma}{ds} \frac{dx^\delta}{ds}$$

Whitehead's theory is an action-at-a-distance theory in Minkowski space-time, particles interacting through retarded gravitational potentials. In 1924, Eddington¹⁴ showed that the equations of motion for the one-body problem in Whitehead's theory are formally identical with the corresponding equations in general relativity if the Schwarzschild metric is represented in a suitable co-ordinate system. Later this suggestion led Schild to construct an infinite set of theories of Whitehead's type, that is, action-at-a-distance theories in Minkowski space-time. The metric tensor for the Schwarzschild solution can be written:

$$\sigma_{ab} = g_{ab} + h_{ab}$$

where g_{ab} is the Minkowski metric tensor, and:

$$h_{00} = -\frac{2GM}{c^2 r}, \quad h_{0a} = h_{a0} = 0,$$

$$h_{ab} = -\frac{2GM/c^2 r}{1 - 2GM/c^2 r} \frac{x^a x^b}{r^2},$$

$r = (x^a x_a)^{1/2}$, and $a, b = 1, 2, 3$. Schild introduces a general transformation $x^0 \rightarrow \bar{x}^0$, $x^a \rightarrow \bar{x}^a$, of the form:

$$x^0 = \bar{x}^0 - \frac{2GM}{c^2} \psi \left(\frac{2GM}{c^2 r} \right)$$

$$x^a = \bar{x}^a \left\{ 1 + \varphi \left(\frac{2GM}{c^2 r} \right) \right\}$$

where $\bar{r} = (\bar{x}^a \bar{x}_a)^{1/2}$. To order $1/c^2$, we write, where b is a constant:

$$\varphi \left(\frac{2GM}{c^2 r} \right) = b \left(\frac{2GM}{c^2 r} \right)$$

Whitehead's original theory corresponds to the choice $\varphi = 0$, $\psi(v) = \log\{v/(1-v)\}$. The paths of test-particles are given by the variational principle:

$$\delta \int d\sigma = 0$$

where

$$d\sigma^2 = \sigma_{ab} dx^a dx^b$$

and light-paths by the condition $d\sigma = 0$. Further, it is assumed that the period of an atom at rest is given by equal intervals σ .

In addition to the above theories, we have also examined a different type of Lorentz-invariant theory due to Poincaré.

Poincaré's Theory

In this theory¹⁶ the inverse-square law of gravitation was re-expressed in Lorentz-invariant form. The equations of motion for a particle of mass m_1 at position x_1^a at time t_1 in the field of a particle of mass m_2 at position x_2^a at time $t_2 = t_1 - r/c$, where $r^2 = (x_1^a - x_2^a)(x_1^a - x_2^a)$, are of the form:

$$\frac{d^2 x_1^a}{ds_1^2} = - \frac{Gm_2}{c^2 r^3} \gamma^n \left(x_1^a - x_2^a - \frac{p_1}{\gamma} \frac{dx_2^a}{ds_2} \right)$$

where

$$p_r = g_{ab} \frac{dx^a}{ds_r} (x_1^b - x_2^b)$$

for $r = 1, 2$, g_{ab} is the covariant Minkowski tensor,

$$\gamma = g_{ab} \frac{dx_1^a}{ds_1} \frac{dx_2^b}{ds_2}$$

and n is a constant.

The One-Body Problem

In the following table for the three Einstein tests (obtained in general relativity from the Schwarzschild metric), the units employed are as follows: (1) the advance of perihelion per revolution is expressed in units of $6\pi GM/c^2 a(1-e^2)$ radians, where M is the mass of the central body, a is the semi-major axis and e the eccentricity of the orbital ellipse; (2) the deflexion of a light-ray is expressed in units of $4GM/c^2 R$ radians, where R is the minimum distance of the light-ray from O the centre of mass of the central body; (3) the gravitational red-shift is expressed by the value assigned to:

$$\frac{\delta\lambda/\lambda}{GM/c^2 r}$$

where λ is the wave-length of a standard spectral line emitted by an atom at 'infinity', that is, where the gravitational field of the central body is negligible, and $\lambda + \delta\lambda$ is the wave-length of the corresponding line emitted by an atom at distance r from O .

Table 1

Theory	Advance of perihelion	Deflexion of light	Gravitational red shift
1. General relativity	1	1	1
2. Nordstrom's (generalized): $\begin{cases} q = 0 \text{ (Nordstrom)} \\ q = 1/2 \text{ (Littlewood, Bergmann)} \\ q = 4 \end{cases}$	$\begin{cases} (q-1)/3 \\ -1/3 \\ -1/6 \\ 1 \\ -1/6 \end{cases}$	$\begin{cases} 1 \\ 0 \\ 0 \\ 0 \\ - \end{cases}$	$\begin{cases} 1 \\ 1 \\ 1 \\ 1 \\ - \end{cases}$
3. Milne's	1	0	1
4. Scalar potential with a variable velocity of light: $\begin{cases} \text{Theory (i)} \\ \text{Theory (ii)} \end{cases}$	$\begin{cases} 2/3 \\ 1 \\ 1/6 \end{cases}$	$\begin{cases} 1/2 \\ 1/2 \\ 0 \end{cases}$	$\begin{cases} 1 \\ 1 \\ 0 \end{cases}$
5. Vector potential: $\begin{cases} p = 0 \\ p > 0 \end{cases}$	$\begin{cases} 1/6 \\ (1+2p)/6 \end{cases}$	$\begin{cases} 0 \\ pmGM/8c^2 R \end{cases}$	$\begin{cases} 0 \\ 1 \end{cases}$
6. Kustaanheimo's*	1	1	1
7. Birkhoff's	1	1	1
8. Whitehead's (generalized) $\begin{cases} n < 2 \\ n > 2 \\ n = 2 \end{cases}$	$\begin{cases} n/6 \\ n/6 \\ 1/3 \end{cases}$	$\begin{cases} 1 \\ 0 \\ 1/2 \end{cases}$	$\begin{cases} 1 \\ 0 \\ 1 \end{cases}$
9. Poincaré's:	1	1	1

*This theory contains a large number of arbitrary parameters. Conditions have been imposed on them *ad hoc* so that the theory predicts the same results as general relativity for all three effects.

The Two-Body Problem

Although it has not proved possible to formulate a complete solution of the two-body problem in general relativity, approximate solutions can be obtained. Levi-Civita¹⁵ reached the conclusion that, to order $1/c^2$, the centre of mass of two unequal bodies would be automatically accelerated along the major axis of the relative orbit, in the direction of the periastron of the larger mass. Since the periastron always slowly revolves, Levi-Civita's result would imply that a binary star considered as a whole would describe a circle. However, when the problem was re-examined by Eddington and Clark¹⁶, working to the same order of approximation, they found that an error had been made by de Sitter in calculating a general formula, used by Levi-Civita, for the line-element due to n bodies. The effect of the resulting correction was to make the secular acceleration of the centre of mass of the two-body system zero, at least to order $1/c^2$.

In 1954, Clark¹⁷ considered the two-body problem in Whitehead's original theory and found that the centre of mass would have a secular acceleration towards the periastron of the more massive component. In his paper in 1955, Schild conjectured that "all theories of Whitehead's type violate the law of action and reaction, and that they all predict a secular acceleration of the centre of mass in the two-body problem". We have found that, although this is true in general, for certain functions φ (all those for which $b = 1/4$) there is, to order $1/c^2$, no secular acceleration of the centre of mass.

In Table 2 are listed the results which we have obtained for the respective theories, correct to order $1/c^2$ for the following:

(1) the acceleration of the centre of mass of a binary system towards the periastron of the orbit of the more massive component expressed as an increase of velocity in this direction per revolution in units of:

$$\frac{\pi G^{3/2} m_1 m_2 (m_1 - m_2) e}{\{ma(1-e^2)\}^{3/2} c^2}$$

cm. per sec. per revolution, where m_1, m_2 are the respective masses, m is the total mass, and a, e are the semi-major axis and eccentricity, respectively, of the relative orbital ellipse; (2) the advance of periastron per revolution expressed in units of $6\pi GM/c^2 a(1-e^2)$ radians.

Table 2

Theory	Acceleration of centre of mass	Advance of periastron
1. General relativity	0	$\frac{1}{3} - \frac{(2q-1)}{3} \frac{m_1 m_2}{m^2}$
2. Nordstrom's (generalized):	$2q-1$	$-\frac{1}{3} + \frac{1}{3} \frac{m_1 m_2}{m^2}$
$q = 0$ (Nordstrom)	-1	$-\frac{1}{3} + \frac{1}{3} \frac{m_1 m_2}{m^2}$
$q = 1/2$ (Littlewood, Bergmann)	0	-1/6
4. Scalar potential with a variable velocity of light:		
Theory (I)	3	$\frac{2}{3} - 2 \frac{m_1 m_2}{m^2}$
Theory (II)	5	$1 - \frac{8}{3} \frac{m_1 m_2}{m^2}$
5. Vector potential	p	$\frac{1+2p}{6} - \frac{p}{3} \frac{m_1 m_2}{m^2}$
6. Kustaanheimo's*	0	1
7. Birkhoff's	1	$1 - \frac{2}{3} \frac{m_1 m_2}{m^2}$
8. Whitehead's (generalized):	$1-4b$	$1 + \frac{(4b-1)}{3} \frac{m_1 m_2}{m^2}$
$b = 0$ (Whitehead)	1	$1 - \frac{1}{3} \frac{m_1 m_2}{m^2}$
$b = 1/4$	0	1
9. Poincaré's	0	$n/6$

* Conditions have been imposed *ad hoc* on the arbitrary parameters in this theory so that it predicts the same results as general relativity for the effects listed in both Table 1 and Table 2.

Additional Effects In the One-body Problem

Two additional effects arise in the one-body problem when due account is taken of the axial rotation of the central body: there is an additional advance of perihelion, and the normal to the plane of the orbit precesses about the axis of rotation of the central body. Effects of this type were first obtained in general relativity by Lense and Thirring¹², working to order $1/c^2$. We have calculated similar effects in Lorentz-invariant theories to the same order of approximation. Since Poincaré's theory was not originally formulated so as to apply to continuous distributions of gravitating matter, we have extended his theory by the same method as that followed by Rayner¹³ in the case of Whitehead's theory in its original form ($b = 0$).

In Table 3 we list for the respective theories:

(1) The additional advance of perihelion, expressed in units of:

$$\frac{2\pi}{5} \frac{(GM)^{1/2}}{\{a(1-e^2)\}^{3/2}} \frac{\omega R^2}{c^2} \cos \alpha$$

radians per revolution, where R is the radius of the central body (a sphere of mass M), ω its angular velocity, α the angle between its axis of rotation and the normal to the plane of the orbit of the test-particle (to the order of approximation considered this angle remains constant in all theories), and a, e are the semi-major axis and eccentricity of the orbital ellipse. (The expression can also be written in the concise form:

$$\frac{(I\omega\omega')}{(Mc^2)} \frac{\pi \cos \alpha}{(1-e^2)^{3/2}}$$

where $I = 2MR^2/5$, that is, the moment of inertia of the homogeneous sphere about a diameter, and ω' is the mean angular velocity in the orbital ellipse.) (2) The rate of precession of the normal to the plane of the orbit about the axis of rotation of the central body, expressed in units of:

$$\frac{\pi}{5} \frac{(GM)^{1/2}}{\{a(1-e^2)\}^{3/2}} \frac{\omega R^2}{c^2}$$

radians per orbital revolution.

In the case of Whitehead's theory, a further advance of perihelion arises due to the fact that the central body is no longer being treated as if it were of zero radius¹⁰. Thus, even if ω were zero the perihelion advance would not be the same as that given by general relativity, but would be:

$$\frac{6\pi GM}{c^2 a(1-e^2)} \left\{ 1 + \frac{(4+e^2)}{10(1-e^2)} \left(\frac{R}{a} \right)^2 \right\}$$

For e^2 small, the ratio of this additional term to the term when $R = 0$ is approximately $2R^2/5a^2$. It is therefore appreciable if a is not too large compared with R .

Conclusions

(1) On inspecting Table 1, we note that the gravitational red-shift is the least sensitive of Einstein's tests for general relativity. The same effect is predicted by almost all Lorentz-invariant theories. For, apart from Poincaré's theory with $n < 2$ and the vector potential theory with $p = 0$, the only exceptions are those theories in which it has not been possible to make the calculation. We may therefore conclude that this effect is essentially a special relativity effect arising when the ideas of that theory are applied to the study of gravitational fields.

(2) On the other hand, with the exception of Kustaanheimo's theory (which contains a large number of unspecified parameters), the only theories which agree with general relativity in their predictions for both the advance of perihelion and the deflexion of light in the one-body problem are the tensor theories of Birkhoff and Whitehead-Schild.

(3) If, however, we take into account the finite radius of the central body, then Whitehead's theory yields an additional term for the advance of perihelion in the one-body problem, irrespective of whether the central body is rotating.

(4) In the case of the two-body problem (Table 2), there arise two highly sensitive tests for general relativity. For, with the possible exception of Kustaanheimo's theory, there is complete agreement with general relativity only in one particular instance of the Whitehead-Schild set of theories and in Poincaré's theory with a particular value of n ($n = 6$).

(5) Turning to Table 3, we note that no theory agrees with general relativity in all five tests of the one-body problem, for even in the case of Whitehead's theory there is a discrepancy due to the effect of the non-zero radius of the central body. The discrepancy between Kustaanheimo's theory and

Table 3

Theory	Additional advance of perihelion due to rotation of central body	Rate of orbital precession
1. General relativity	-8	8
2. Nordstrom's (generalized)	0	0
5. Vector potential	$-(p+2)$	$p+2$
6. Kustaanheimo's*	-6	arbitrary
7. Birkhoff's	-6	6
8. Whitehead's†	-8	8
9. Poincaré's	$-(n+1)$	$n+1$

* Conditions have been imposed *ad hoc* on the arbitrary parameters in this theory so that it predicts the same results as general relativity for the effects listed in both Table 1 and Table 2.

† We have considered here the only original Whitehead theory.

general relativity is particularly striking in view of the large number of arbitrary parameters occurring in the former theory. Whatever particular values are assigned to these parameters to make the predictions of that theory agree with those of general relativity in Tables 1 and 2, it is impossible to make the two theories agree in the first column of Table 3.

(6) We may therefore conclude that no Lorentz-invariant theory of gravitation predicts all the effects considered here in complete agreement with general relativity.

(7) Finally, as regards possible practical application, it is of interest to consider the orders of magnitude of the respective effects for artificial satellites moving in orbits about the Earth with suitably chosen values of α . For an artificial satellite moving around the Earth at a mean height above the surface of the order of 1,000 km., the advance of perigee (uncorrected for the effect of the Earth's rotation) is of the order 10 sec. of arc per year, whereas the rotation correction effect is of the order 0.3 sec. of arc per year in the case of general relativity. The biggest observable discriminating effect would arise,

however, in connexion with the additional advance of perigee in Whitehead's theory due to the finite radius of the Earth. For this could amount to about a quarter of the uncorrected advance, whereas it would be zero in the case of general relativity.

UTILIZATION OF NITRIC OXIDE BY MICRO-ORGANISMS AND HIGHER PLANTS

By C. A. FEWSON and DR. D. J. D. NICHOLAS*

Chemical Microbiology Department, Long Ashton Research Station, University of Bristol

ALTHOUGH the metabolism of inorganic nitrogen compounds has been the subject of intensive investigation in recent years, the intermediates have not been unequivocally identified. It is generally considered that nitrate assimilation and nitrification occur in a series of two-electron steps¹⁻³. Nitric oxide, which is formed by a one-electron reduction of nitrite, has long been recognized as a product of denitrification^{4,5}; but it has not been suggested as an intermediate in the assimilatory reduction of nitrate^{3,6}. During the course of work on the dissimilatory reduction of nitrate by *Pseudomonas aeruginosa*⁷⁻⁹ and the assimilation of nitrate in *Neurospora crassa*⁸, we have obtained evidence that nitric oxide may well be a common intermediate, and we have therefore re-examined the position of nitric oxide in various pathways of inorganic nitrogen metabolism.

Denitrification

Several early workers²⁻¹¹ reported the production of brown fumes during the fermentation of beet and identified them as nitrogen dioxide formed by the oxidation of nitric oxide. More recently nitric oxide has been found to be a product of denitrification in soil^{12,13} and also in silage fermentation¹⁴. Bacteria known to produce nitric oxide during the dissimilatory reduction of nitrate or nitrite include *Bacillus licheniformis*¹⁵, *Thiobacillus denitrificans*¹⁶, *Pseudomonas aeruginosa*⁹ and *Micrococcus denitrificans*¹⁷. There have also been several reports of the production of nitrogen gas from nitric oxide by bacteria¹⁸⁻²⁰. Chung and Najjar¹⁸ partially characterized a nitric oxide reductase from *P. stutzeri* and concluded that it was a flavoprotein requiring both iron and copper

for its activity. The dialysis techniques used by these workers to establish the metal requirements are open to question since iron, copper and, to a smaller extent, zinc reactivated the enzyme after it had been subjected to prolonged dialysis against salicylaldoxime. The metal effects could therefore have resulted from the removal of residual chelate bound to the enzyme since the reversal of the inhibition was in the order of the affinities of the metals for salicylaldoxime.

Nitric oxide reductase purified 25-fold from *P. aeruginosa*, as shown in Table 1, is a metallo-flavo-protein⁷. The activity of the purified enzyme, which utilized reduced pyocyanine but not reduced pyridine nucleotides as the hydrogen donor, was maximal at pH 8.0. Sulphydryl groups appear to be required for the enzyme activity since glutathione partially offset the inhibition of *p*-chloromercuribenzoate, as shown in Table 2. A flavin requirement for the enzyme was indicated by the reversal of mepacrine inhibition with flavin mononucleotide (FMN) or flavinadenine dinucleotide (FAD) and confirmed by precipitating the enzyme three times with ammonium sulphate (pH 7.0), when its activity, diminished by about 70 per cent, was reconstituted by FMN or FAD (Michaelis-Menten constant, $K_m = 4 \times 10^{-6}$ M). At a concentration of 2×10^{-3} M the iron and copper chelating agents, α, α' -dipyridyl, *o*-phenanthroline, potassium ethyl xanthate and 2:9 dimethyl 1:10 phenanthroline, inhibited the enzyme by more than 40 per cent. Salicylaldoxime, α -benzoin oxime and sodium diethyl-dithiocarbamate, however, which chelate copper but not iron between pH 7 and 8 (ref. 20), reduced the enzyme activity by less than 10 per cent. There is some evidence for the concentration of iron, but not

* Member of the scientific staff of the Agricultural Research Council seconded to the University of Bristol.

Table 1. PURIFICATION OF NITRIC OXIDE REDUCTASE FROM *Pseudomonas aeruginosa*

Fraction	Procedure	Volume (ml.)	Total protein (mgm.)	Protein* (mgm./ml.)	Total units (μ l. NO/hr.)	Specific activity (μ l. NO/mgm. protein/hr.)	Recovery (per cent)	Purification
1	Supernatant solution after centrifuging at 18,000 g	17.5	301	17.2	1,850	4.5	—	—
2	Precipitate from 0-43 per cent ammonium sulphate saturation of Fraction 1, centrifuged at 5,000 g for 5 min, dissolved in 0.005 M phosphate buffer (pH 8.0)	17.5	155	8.86	1,280	8.1	93	1.8
3	Fraction 2 was added to a diethylamino-ethyl cellulose column. The column was eluted with 20 ml. aliquots of 0.01 M phosphate buffer (pH 8.0). Activity of the fourth aliquot	22.0	8.6	0.39	960	118.5	71	25

Actively denitrifying cells of *P. aeruginosa* (NCIB 8704) were grown in a nitrate-peptone medium (ref. 27) under anaerobic conditions for 24 hr. at 37° C. The harvested cells were washed and stored at -15° C. 5 gm. frozen cells were suspended in 5 ml. 0.1 M phosphate buffer (pH 8.0) and disrupted with an ultrasonic probe (20 kc./sec.) for 15 min. at 4° C. The homogenate was diluted to 20 ml. with the same buffer and centrifuged at 18,000 g for 45 min. The supernatant solution was used as the source of the crude enzyme. The enzyme activity was assayed using the following Warburg reaction mixture. Main vessel, 1.0 ml. enzyme, 1.1 ml. 0.1 M phosphate buffer (pH 8.0), 0.1 ml. 10⁻⁴ M pyocyanine; side-arm, 0.1 mgm. crystalline alcohol dehydrogenase, 0.1 ml. 2 per cent v/v ethyl alcohol, 0.1 ml. (300 μ M) reduced diphosphopyridine nucleotide; centre well, 0.2 ml. 20 per cent w/v potassium hydroxide. Gas phase, 25 per cent NO/75 per cent nitrogen. Temp. 30° C. Boiled enzyme controls were included. Protein contents were determined by the Folin method (ref. 28).

copper, in partially purified preparations of the enzyme. Extracts of cells deficient in iron contained decreased nitric oxide reductase activity (25 per cent of normal cells) whereas those of cells deficient in copper, molybdenum, zinc or manganese were unaffected. It seems unlikely, therefore, that copper is required for nitric oxide reductase activity in this organism.

Nitrate Assimilation

McNall and Atkinson²¹ showed that *Escherichia coli* B, which reduced nitrate but not nitrite, did not reduce nitric oxide. After repeatedly subculturing the organism on a nitrate medium they obtained a strain (*E. coli*, Bn) which could utilize nitrate or nitric oxide as the sole nitrogen source for growth. Similarly Steinberg²² succeeded in growing *Aspergillus niger* and *Nicotiana tabacum* on nitrohydroxylamine (N_2O_2^-) which is a hydrate of nitric oxide. We have therefore examined a range of bacteria, fungi, algae and higher plants to determine whether nitric oxide reductase activity is a universal enzyme in organisms which assimilate nitrate. The results in Table 3 show that the uptake of nitric oxide by cells and their extracts was limited to organisms grown with nitrate. Micro-organisms grown on ammonium-nitrogen only showed little or no nitric oxide reductase activity. The effect with higher plants was less clear because of the difficulty of growing them in the complete absence of nitrate or nitrite which are almost invariably produced in the culture solution by nitrifying

organisms. Indeed, the majority of plants showed undiminished nitrate and nitric oxide reductase activities when grown on ammonium-nitrogen under non-sterile conditions. Roots of wheat seedlings, however, grown under strictly aseptic conditions with nitrate, had five times the enzyme activity of those grown with ammonium chloride as the only nitrogen source. The rate of nitric oxide uptake was very similar to that of nitrate reduction in the same homogenates of micro-organisms or higher plants, for example, *Neurospora crassa* grown on a nitrate medium had a nitric oxide reductase activity of 15 μ l. NO (650 μ M NO)/mgm. N/hr. and a nitrate reductase activity of 580 μ M NO₂⁻ reduced/mgm. N/hr.

Although nitrite reductases from *Neurospora* and higher plants have been studied in some detail³ the

Dr. H. R. Davenport supplied the *C. equisetifolia*.

product of the reduction has not hitherto been identified. Walker, of this laboratory, however, using the nitrite reductase from *Neurospora*, has shown that there is a stoichiometric reduction of nitrite to nitric oxide (unpublished work).

Nitrogen Fixation and Nitrification

During the course of investigations on the utilization of nitric oxide it became evident that nitrogen-fixing organisms possessed an active nitric oxide reductase, as shown in Table 4. Thus the bacteria *Azotobacter vinelandii* and *Clostridium pasteurianum* and the blue-green algae *Anabaena cylindrica* and *Nostoc muscorum* all took up nitric oxide when grown with nitrogen gas or nitrate-nitrogen, but not when grown with ammonium-nitrogen. Similarly the nodular tissue of the legume *Vicia faba* (broad bean) and of the non-legume *Casuarina equisetifolia* utilized the gas more rapidly than did the neighbouring root tissue. Nitric oxide inhibited the hydrogenase activity of *A. vinelandii* and *C. pasteurianum* when methylene blue was the hydrogen acceptor¹⁸, but sodium nitrate, nitrite or hyponitrite, nitrous oxide, hydroxylamine or ammonium sulphate were without effect.

Anderson, of this Station, has shown that cell-free extracts of *Nitrosomonas europaea*, which oxidize hydroxylamine to nitrite aerobically²⁴, produce nitric oxide under anaerobic conditions (unpublished work).

Conclusions

The results presented in this paper support the view that nitric oxide, or a compound with which it equilibrates, is an intermediate in both assimilatory

and dissimilatory nitrate reduction. The significance of the nitric oxide uptake in nitrogen-fixing organisms is less clear, but *Rhizobium*, *Azotobacter* and *Clostridium* also contain nitrate, nitrite and hydroxylamine reductases^{17,25,26} and these enzymes could all be induced by nitric oxide should it be formed by an initial oxidative step in the fixation process. Preliminary results indicate that nitric oxide may also be formed during the nitrification of hydroxylamine. Thus nitric oxide may well be a key intermediate in the metabolism of inorganic nitrogen compounds in micro-organisms and in higher plants.

One of us (C. A. F.) gratefully acknowledges the receipt of a postgraduate scholarship from the Ministry of Agriculture, Fisheries and Food. We are also grateful to Messrs. D. J. Fisher, W. J. Redmond and M. A. Wright for assistance with some of the experiments.

PRESENCE OF CELL WALLS LIKE THOSE OF BACTERIA IN RICKETTSIAE

By DR. A. C. ALLISON and DR. H. R. PERKINS

National Institute for Medical Research, London, N.W.7

THERE has been uncertainty about the taxonomic position of *Rickettsiae*, organisms that produce disease in man and parasitize a wide range of animals. All pathogenic *Rickettsiae* are considered to be obligate intracellular parasites, and no unequivocal evidence has been obtained of their multiplication in cell-free media. Under the light microscope *Rickettsiae* appear as small Gram-negative rods in the cytoplasm of infected cells. When examined by the electron

microscope in air-dried preparations and in ultra-thin sections the organisms appear to have double limiting membranes¹. Preparations of membranes of *Rickettsia mooseri* were made by Schaechter *et al.*², who reported that they contain amino-acids, glucose, hexosamine, glucuronic acid and galactose. These compounds are present in a wide range of organisms, but all bacteria so far studied—and only bacteria—have as a component of their cell walls mucopeptides

containing muramic acid³. In the present work, membranes of *R. burneti* have been shown to have muramic acid, and like the cell walls of bacteria to be digested by lysozyme.

Rickettsia (Coxiella) burneti was grown in embryonated eggs, inoculated at 6 days and harvested after a further 6 days incubation at 35°. Tests for bacterial contamination were negative. Suspensions of organisms were purified as described elsewhere⁴, omitting formalin treatment. The suspensions were incubated with 1 per cent sodium deoxycholate in 0.1 M tris (hydroxymethyl) amino-methane buffer, pH 7.0, for 4 hr. at 45° with constant agitation. Cell-wall preparations similar to those described by Schaechter *et al.* were obtained. These preparations were not morphologically changed by digestion at 37° for 2 hr. with crystalline trypsin (Armour) at a concentration of 100 µgm. per ml. in 0.1 M tris buffer, pH 7.6. However, digestion for 2 hr. with crystalline egg-white lysozyme, 50 µgm. per ml. in 0.1 M tris buffer, pH 8.0, containing 0.01 M sodium ethylenediamine tetraacetate, resulted in the disappearance of morphologically recognizable cell walls. These are the conditions under which lysozyme digests the walls of Gram-negative bacteria⁵. No precipitation was visible and digestion with heated enzyme did not change the appearance of the cell walls, from which it seems unlikely that aggregation in the presence of the highly basic protein, lysozyme, was responsible for their disappearance. Lysozyme was also shown to liberate material giving a reaction for N-acetyl amino-sugars from suspensions of *R. burneti*, just as it does from the cell walls of many species of bacteria⁶. Suspensions of *R. burneti* were treated with egg-white lysozyme under the conditions described above for 3 hr. at 37°. The material was brought to pH 9.0 and shown to contain material giving the Morgan-Elson reaction for N-acetyl amino-sugars⁷.

Analyses of suspensions of *R. burneti* have also established that they contain muramic acid. The organisms were precipitated with 5 per cent w/v trichloroacetic acid. The precipitates were hydrolysed in sealed ampoules with 4 N hydrochloric acid at 105° for 4 hr. After removal of excess hydrochloric acid *in vacuo*, hexosamines in the hydrolysates were first concentrated by chromatography on a column of 'Dowex 50' (H⁺). The hexosamine peak was transferred to a charcoal-'Celite' column, and glucosamine was eluted with water⁸. The 10 per cent ethanolic eluate, subjected to paper chromatography in butanol-pyridine-water (6:4:3), showed a spot in the position expected of muramic acid. Material eluted from this spot when submitted to the Elson-Morgan test⁹ gave an absorption curve with a maximum at 510 mµ (505 mµ overnight), identical with that of authentic muramic acid isolated from the cell walls of *Staphylococcus aureus* and unlike that of glucosamine (Fig. 1). Such a curve is typical of hexosamines substituted at position 3 (ref. 10), and muramic acid is the only naturally occurring material of this type likely to have withstood the conditions of hydrolysis used. Furthermore, both the acetylated derivative and the substituted pentose obtained on treatment with ninhydrin under appropriate conditions¹¹ showed identical mobilities on paper chromatography with those of authentic muramic acid derivatives.

Preliminary tests have shown that muramic acid is present in *R. typhi* grown under the same conditions as *R. burneti* and in the mouse pneumonitis

Fig. 1. Absorption curves in Randle and Morgan tests of: A, authentic muramic acid from *Staphylococcus aureus*; B, material from *Rickettsia burneti*; C, glucosamine

organism (Nigg) grown in mouse embryo cell cultures; the latter belong to the psittacosis-lymphogranuloma group. No trace of muramic acid was detectable in control preparations from uninfected yolk sacs, or in highly concentrated suspensions of vaccinia virus grown in chorioallantoic membranes or influenza virus grown in the allantois of embryonated eggs.

The present work has shown that *Rickettsias* have cell walls similar to those of bacteria. Since penicillin inhibits bacterial cell wall synthesis¹², the sensitivity of the *Rickettsia* and psittacosis-lymphogranuloma groups of organisms to penicillin may be attributable to their possession of cell walls of this type. In a number of other respects these organisms resemble bacteria rather than true viruses: (1) they have both deoxyribonucleic acid and ribonucleic acid^{3,13}, whereas true viruses have one or the other (Allison, A. C., and Burke, D. C., unpublished observations); (2) they multiply by binary fission¹⁴, which is not the case in the true viruses; (3) they are sensitive to chloramphenicol and tetracyclines, and purified suspensions of organisms have some capacity for incorporation of amino-acids into protein, which is abolished by chloramphenicol¹⁵.

All these findings suggest that *Rickettsias* are probably bacteria that have become adapted to intracellular multiplication. Perhaps they have lost the capacity to synthesize certain enzymes necessary for growth and replication, and so have become

obligate intracellular parasites. The apparent inability of suspensions of *Rickettsiae* to utilize glucose, even though they can metabolize tricarboxylic acid cycle intermediates¹⁶, may be a case in point. There is a substantial body of opinion that *Rickettsiae* were originally insect parasites, and among the *Rickettsiae* of insects there seems to be no sharp line of distinction between intracellular and free-living forms¹⁷.

We are indebted to Drs. P. Bradstreet, E. B. Jackson, J. Marshall and to Lederle Laboratories, Inc., for providing suspensions of some of the organisms studied, and for electron micrographs of preparations.

IDENTIFICATION OF THE RECOMBINANT PRODUCTS OF CANINE AND HUMAN HÆMOGLOBINS

By ELIZABETH A. ROBINSON and DR. HARVEY A. ITANO

National Institute of Arthritis and Metabolic Diseases of the National Institutes of Health, Public Health Service, Bethesda, Maryland

WHEN a mixture of canine carbonmonoxyhæmoglobin and human carbonmonoxyhæmoglobin A is dissociated at either pH 4.7 (ref. 1) or pH 11.0 (ref. 2) for 20 min. or more and then recombined at neutral pH, two additional electrophoretic components are produced. In slightly acidic buffer, in which all the components are cationic, canine hæmoglobin migrates more slowly than hæmoglobin A; one of the new components migrates more slowly than canine hæmoglobin; and the other migrates more rapidly than hæmoglobin A (Figs. 1 and 3). The exchange reaction:

though it accounts for the appearance of two new components, does not specify which of the postulated products corresponds to the new fast or the new slow electrophoretic component. Probable compositions of these components have now been determined by recombination of canine hæmoglobin with human hæmoglobins known to be abnormal in either the α -chain or the β -chain.

All dissociations of the equimolar mixtures of canine-human carbonmonoxyhæmoglobin to be described were done at pH 4.7, $\Gamma/2$ 0.10 (acetate buffer) for 24 hr. except where otherwise noted. Dissociation was followed by dialysis in potassium phosphate buffer of pH 6.8, $\Gamma/2$ 0.02 or pH 6.3, $\Gamma/2$ 0.02 at 5° C. for approximately 18 hr. The control and recombined 1 per cent carbonmonoxyhæmoglobin mixtures were analysed by moving-boundary electrophoresis in the same phosphate buffer used for dialysis for 5 hr. at 0.5° with potential gradients of 9.3 (at pH 6.8) and 8.5 (at pH 6.3) V./cm.

A recombined mixture of canine and S hæmoglobins showed little change in the electrophoretic pattern other than asymmetry of the faster (S) boundary. Electrophoresis of a recombined mixture of canine and C hæmoglobins showed one new component migrating between canine and C in the approximate position of

hæmoglobin A and asymmetry of the fastest (C) boundary. Recombination of a mixture of canine, S, and C hæmoglobins which had been dissociated for

Fig. 2. Ascending limb electrophoretic patterns of 1 per cent carbonmonoxyhaemoglobin in phosphate buffer of pH 6.8, I/2 0.02. The direction of migration is from right to left. a, C, S, canine control; b, C, S, canine recombined; c, C, A, canine control; d, C, A, canine recombined. b and d were recombined after dissociation for 4 hr.

4 hr. yielded one new component in the approximate position of haemoglobin A with merging of the original S and C boundaries into one fast unsymmetrical boundary. No component migrating more slowly than canine or more rapidly than C appeared in these experiments. Dissociation (4 hr.) and recombination of a mixture of canine, A, and C haemoglobins gave one new electrophoretic component migrating more slowly than canine.

At pH 6.3, haemoglobin I migrates more slowly than canine haemoglobin. Recombination of a dissociated canine-I haemoglobin mixture (I was isolated from an A-I sample by column chromatography³) again yielded only two electrophoretic components, but both boundaries were decidedly skewed and were more widely separated from each other than in the control experiment. Hopkins-2 haemoglobin (partially purified from Hopkins-2 trait by column chromatography³) migrates with canine haemoglobin as one electrophoretic component at pH 6.3. On dissociation and recombination a new component migrating more slowly than canine and Hopkins-2 was observed as well as an increase in the proportion and mobility of the component in the position of haemoglobin A. A new fast component was also present, but the amount was much less than in the canine-A experiments. The electrophoretic patterns of all experiments are shown in Figs. 1, 2, and 3.

Not one of the results is as clear-cut as the results of I-S⁴ and canine-A recombinations, in which each reactant and product was resolved as a separate electrophoretic component. A self-consistent interpretation is nevertheless possible if the observed results and the postulated products of all recombinations are correlated. The exchange reactions of canine haemoglobin with haemoglobins S and C, which have altered β -chains^{5,6}, and with haemoglobins I⁷ and Hopkins-2 (ref. 1), which have altered α -chains, can be represented as follows:

The new electrophoretic component of lower mobility than canine haemoglobin in the canine-A recombination did not appear in either the canine-S or the canine-C recombinations. $\alpha_2^{\text{can}}\beta_2^{\text{A}}$, a product of reaction (1), but not of reactions (2) or (3), must therefore be the new slow component, and $\alpha_2^{\text{A}}\beta_2^{\text{can}}$, the common product of all three recombinations, must be the new fast component. The mobility of $\alpha_2^{\text{A}}\beta_2^{\text{can}}$ probably lies between those of S and C since it is not resolved electrophoretically from either. Consideration of reactions (4) and (5) adds support to identification of the new fast component as $\alpha_2^{\text{A}}\beta_2^{\text{can}}$. This species, which is not postulated as a product in either reaction, was absent in the canine-I recombined mixture and was present in the canine-Ho-2 recombined mixture only in an amount compatible with the proportion of haemoglobin A known to be present as a contaminant before recombination. A new electrophoretic component appeared in the canine-Ho-2 recombination in the same position and amount as the new slow component of the canine-A recombination, a result consistent with the identification of the new slow component as $\alpha_2^{\text{can}}\beta_2^{\text{A}}$ since it is a postulated product in both reactions (1) and (5). No new electrophoretic component was resolved in the canine-I recombination; however, the presence of $\alpha_2^{\text{can}}\beta_2^{\text{A}}$ as postulated by reaction (4) is not excluded because the mobility of this species is similar to that of I.

Identification of the new fast component of the canine-A recombination as $\alpha_2^{\text{A}}\beta_2^{\text{can}}$ and the new slow component as $\alpha_2^{\text{can}}\beta_2^{\text{A}}$ permits estimation of the

Table 1. COMPOSITION OF CANINE AND HUMAN HEMOGLOBIN MIXTURES BEFORE AND AFTER RECOMBINATION

Mixture		Electrophoretic Composition (in order of increasing mobility)
can + A	Control	41% $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 59% $\alpha_2^{\text{A}}\beta_2^{\text{A}}$
	Recombined	31% $\alpha_2^{\text{can}}\beta_2^{\text{A}}$; 24% $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 21% $\alpha_2^{\text{A}}\beta_2^{\text{A}}$; 24% $\alpha_2^{\text{A}}\beta_2^{\text{can}}$
can + S	Control	50% $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 50% $\alpha_2^{\text{A}}\beta_2^{\text{S}}$
	Recombined	54% $\alpha_2^{\text{can}}\beta_2^{\text{S}}$ + $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 46% $\alpha_2^{\text{A}}\beta_2^{\text{S}}$ + $\alpha_2^{\text{A}}\beta_2^{\text{can}}$
can + C	Control	49% $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 51% $\alpha_2^{\text{A}}\beta_2^{\text{C}}$
	Recombined	20% $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 22% $\alpha_2^{\text{can}}\beta_2^{\text{C}}$; 52% $\alpha_2^{\text{A}}\beta_2^{\text{C}}$ + $\alpha_2^{\text{A}}\beta_2^{\text{can}}$
can + I	Control	40% $\alpha_2^{\text{I}}\beta_2^{\text{A}}$; 60% $\alpha_2^{\text{can}}\beta_2^{\text{can}}$
	Recombined	44% $\alpha_2^{\text{I}}\beta_2^{\text{A}}$ + $\alpha_2^{\text{can}}\beta_2^{\text{A}}$; 56% $\alpha_2^{\text{can}}\beta_2^{\text{can}}$ + $\alpha_2^{\text{I}}\beta_2^{\text{can}}$
can + Ho-2 (+ A)	Control	80% $\alpha_2^{\text{Ho-2}}\beta_2^{\text{A}}$ + $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 20% $\alpha_2^{\text{A}}\beta_2^{\text{A}}$
	Recombined	31% $\alpha_2^{\text{can}}\beta_2^{\text{A}}$; 37% $\alpha_2^{\text{Ho-2}}\beta_2^{\text{A}}$ + $\alpha_2^{\text{can}}\beta_2^{\text{can}}$; 23% $\alpha_2^{\text{A}}\beta_2^{\text{A}}$ + $\alpha_2^{\text{Ho-2}}\beta_2^{\text{can}}$; 9% $\alpha_2^{\text{A}}\beta_2^{\text{can}}$

mobilities of the other products postulated in reactions (2) to (5) if it assumed that the mobilities of $\alpha_2^{\text{A}}\beta_2^{\text{can}}$, $\alpha_2^{\text{Ho-2}}\beta_2^{\text{can}}$ and $\alpha_2^{\text{I}}\beta_2^{\text{can}}$ are related in the same way as those of haemoglobins A, Ho-2 and I, and that the mobilities of $\alpha_2^{\text{can}}\beta_2^{\text{A}}$, $\alpha_2^{\text{can}}\beta_2^{\text{S}}$ and $\alpha_2^{\text{can}}\beta_2^{\text{C}}$ are related in the same way as those of haemoglobins A, S and C. The probable composition of each electrophoretic component in a recombined mixture can then be determined as shown by the following example. No new component was resolved in the S-canine recombination, and one new component with the mobility of haemoglobin A appeared in the canine-C recombination. The new component of the canine-C recombination must be $\alpha_2^{\text{can}}\beta_2^{\text{C}}$ since the other postulated product is $\alpha_2^{\text{A}}\beta_2^{\text{can}}$, which migrates more rapidly than A. Thus the mobility of canine haemoglobin lies between the mobilities of $\alpha_2^{\text{can}}\beta_2^{\text{A}}$, the new slow component of the canine-A recombination, and $\alpha_2^{\text{can}}\beta_2^{\text{C}}$. According to the relative cationic mobilities of haemoglobins A, S and C (A < S < C) the mobility of $\alpha_2^{\text{can}}\beta_2^{\text{S}}$ also lies between the mobilities of $\alpha_2^{\text{can}}\beta_2^{\text{A}}$ and $\alpha_2^{\text{can}}\beta_2^{\text{C}}$. Consequently the slow component in the recombined S-canine mixture

is probably composed of two species of similar mobility, canine haemoglobin and $\alpha_2^{\text{can}}\beta_2^{\text{S}}$. The constituent or constituents of the electrophoretic components in all recombined mixtures were determined in this manner and the results summarized in Table 1. It is seen that the observed proportions of the components are consistent with their postulated compositions and with asymmetrical recombination.

Knowledge that the new slow component of the canine-A recombination carries the β -chain of haemoglobin A, and the new fast component the α -chain, makes possible the use of canine haemoglobin to identify the aberrant chain of an abnormal human haemoglobin. Its advantages for this purpose over previously characterized abnormal haemoglobins such as S and C are that it differs from haemoglobin A in both chains and is readily available in large quantity. If, for example, a human haemoglobin is normal in the α -chain (α^{A}) but altered in the β -chain, recombination of this haemoglobin with canine haemoglobin should yield the same new fast component of the canine-A experiments ($\alpha_2^{\text{A}}\beta_2^{\text{can}}$), but the other new component should migrate in a position different from that of $\alpha_2^{\text{can}}\beta_2^{\text{A}}$. Recombination of fetal haemoglobin ($\alpha_2^{\text{A}}\gamma_2$)⁸⁻¹⁰ and canine haemoglobin yielded just such a result although the relative mobilities of haemoglobins A and F are such that $\alpha_2^{\text{A}}\beta_2^{\text{A}}$ and $\alpha_2^{\text{can}}\gamma_2$ migrate in nearly identical positions (Fig. 4). It would be of interest to investigate such haemoglobins as H (β_4^{A})¹¹ and 'Bart's' (γ_4)¹² in this manner.

determination of the voltage distribution since the fact that the oscillator becomes stabilized at a finite amplitude at all is a consequence of the non-linearity of the system.

In order to obtain meaningful results great care has to be taken to ensure that the line is correctly matched and that the measuring probe presents an effective open-circuit to the structure. Although the latter condition was realized in these measurements some slight standing wave was present on the line. The amplitude of this was, however, small and does not affect the conclusion drawn above.

GEOPHYSICS

Physical Parameters of the Atmospheric Escape Layer

Nicolet¹ and Urey² have made estimates of such physical parameters of the atmospheric escape layer as the height of this critical level, its temperature, and the corresponding scale height, by extrapolation of results of the Rocket Panel³. Since the data of the Rocket Panel extend to a height of only 220 km., considerable extrapolation is necessary. Recent results obtained by observation of satellite orbits extend to altitudes sufficiently high to permit direct inference of physical parameters of the atmosphere at the critical level. It is the purpose of this communication to report such results from the data of King-Hele and Walker⁴; the salient feature which emerges is a diurnal variation in the physical parameters associated with the escape layer.

From a result of Spitzer⁵, the height ζ of the escape layer above the Earth's surface is fixed by the requirement that:

$$nh = (\pi \sigma^2)^{-1} \quad (1)$$

at this level, where n is the number density of atmospheric particles, h is the scale-height, and σ is the mean collision diameter of an atmospheric particle. The analysis of King-Hele and Walker yields the scale height h directly, but not the number density n . The latter quantity is fixed in terms of the directly inferred density ρ of the atmosphere by:

$$n = (\rho/M)N \quad (2)$$

where N is Avogadro's number and M is the mean molecular weight of the air. In default of measurements by mass spectrometer at these high altitudes, one must estimate M , which introduces a basic uncertainty into the results. In agreement with King-Hele and Walker, M will be taken as 22 at a height of 200 km., decreasing linearly with height to $M = 16$ at 500 km., and constant thereafter. Urey's choice $\sigma = 3.15 \times 10^{-8}$ cm. will be taken for the mean collision diameter².

As computed on this basis, the values of nh from the data of King-Hele and Walker are shown as a function of altitude in Fig. 1. Above a height of 300 km., the data points fall on two branches, corresponding to day and night, which actually represent averages for early afternoon and past midnight, respectively. The corresponding heights ζ of the escape layer determined by equation (1) are shown in the second column of Table 1. One notes that ζ is greater for day than for night conditions. This fact is in qualitative accord with my result⁶ that the height

Fig. 1. The parameter nh and the absolute temperature T in the atmosphere as a function of altitude for day and night conditions, from the data of King-Hele and Walker

A Silicon γ -Ray Spectrometer

CURRENT pulses produced by the passage of an ionizing particle through a semi-insulator have been reported in the literature¹. Since most of these materials are, as yet, not available in commercial quantities, we decided to investigate the use of high-resistivity silicon, available as 5,000 ohm cm. p type. We estimated that current pulses of about 10^6 ion pairs might be detectable, particularly if the specimen volume is restricted, and the working temperature is lowered to that of liquid air.

Ohmic contacts are made to the specimen by alloying into a boron-diffused surface layer with gold-gallium wire. A number of devices have been prepared most of which detect radiation. The variation of performance between detectors indicates that the processing is not yet under complete control. However, the following performances have been recorded. Gamma-rays from cobalt-60 have produced pulses up to a maximum of 2 mV., for which the signal to noise ratio is greater than 50 at liquid air temperatures, offering the possibility of high-resolution spectroscopy. Other specimens have detected 1-MeV. γ -radiation and 4-MeV. alpha-rays at room temperature, with a signal to noise ratio suitable for monitoring purposes. The current pulses have duration of a few μ sec. There is a certain amount of indirect evidence that the thermal cycling programme inherent in the boron diffusion process is modifying the carrier life-time and the compensation of the material²⁻⁴. This possibility, together with the effect of surface states, is being investigated as essential for production of reproducible devices.

We wish to thank Mr. J. A. Raines for his advice on the diffusion techniques, and Mr. T. James for assistance in fabricating the counters. Permission to publish this communication has been granted by the Admiralty.

ENGINEERING

Operation of the Backward-Wave Oscillator

WE have recently made some measurements of the voltage distribution along the slow-wave circuit of our 'travelling-wave-tube analogue', operated as a backward-wave oscillator, which are of interest in helping to decide between the various theoretical models which have been proposed to describe backward-wave oscillator operation.

The travelling-wave-tube analogue was described in detail in a recent paper¹, and is based on the lumped circuit travelling-wave tube first described by Matthews². Briefly it consists of a series of drift tubes inside a vacuum envelope interconnected with a series of inductance coils which are outside the vacuum envelope (Fig. 1). The coil-drift tube system simulates an LC delay line the parameters of which can be adjusted to represent those of a normal, practical slow-wave structure. The advantage of the system is that the slow-wave structure properties can be varied, by changing the coils, without breaking the vacuum as would be necessary in the case of a conventional tube. The structure is matched at the opposite end from the gun by means of a high-frequency carbon resistor of appropriate value, while signal is fed on to, or coupled off from, the gun end (according to whether operation is in the forward or backward mode) via a simple T-section network.

Whether the system operates as a forward-wave amplifier, or a backward-wave amplifier or backward-wave oscillator, depends on the electron gun voltage, that is, on choosing the electron velocity so that the electron beam travels in synchronism with the appropriate harmonic. With the particular delay line used, backward-wave operation was obtained for gun voltages ranging between about 200 and 700 volts corresponding to currents of the order of a few milliamperes. No additional attenuation was added to the slow-wave structure—the intrinsic attenuation being sufficient to inhibit operation in spurious modes. The start-oscillation current was found to be about 1.7 mA. and the oscillation frequency about 300 Mc./s., while the coupling impedance of the first backward mode was about 200 ohms, corresponding to an effective C value (Pierce's travelling-wave tube gain parameter) of about 0.06 at start-oscillation.

The voltage along the slow-wave structure was measured by means of a coaxial diode probe mounted on a sliding carriage inside the focusing solenoid, enabling it to be connected to each section in turn. Curves of the voltage distribution obtained are shown in Fig. 2. While the mean trend of the points from collector to gun end is exponential, the falling off of voltage in the half-section at the gun end, the minimum occurring in the region of section 3 and the maximum in the neighbourhood of section 7, are all significant and accord very well with the results of the non-linear theory published by Rowe³. Comparison of these curves with those of Rowe show a striking similarity, allowing for the fact that our measurements could only be made at discrete points along the structure.

It is quite clear that at least a 3-mode theory is necessary to explain the operation and that a 2-mode theory of the type discussed by Gould⁴, although it indicates the right value of starting current, does not predict the correct voltage distribution on the line. It is also important to consider non-linear terms in the

Fig. 1. The lumped circuit backward-wave oscillator analogue

Fig. 2

typical pictures: (a) is taken in the symmetry plane of the torus with helium gas at 50 torr pressure when the plasma current has reached its peak value at 25 k.amp. At higher pressure it is necessary to pre-ionize the gas by running a pulsed discharge current of 100 amp. between a number of internal electrodes placed around the torus. Fig. 2b shows half of a circular discharge at 400 torr. The picture is taken at an angle to the symmetry plane at the peak value 17 k.amp. of the circulating current. Streak camera pictures indicate that when the gas pressure is high, the plasma looks more regular and stable than at low pressures. Further experiments are in preparation.

We thank Prof. N. Herlofson and Mr. C.-G. Fälthammar for many discussions. Mr. R. Johansson has taken part in the experiments.

Motion of Molecules in Very Thin Films between Sliding Surfaces

C. L. GAINES¹ has recently discussed the motion which long-chain polar molecules in mono-molecular layers on solid surfaces may undergo. His work leads to considerations of lubrication phenomena which he reports in progress.

Some results which may be related to the study have occurred in sliding studies of optically flat lapped steel surfaces, where the film thickness of stearic acid was that of only several molecular layers.

Information on the structure of the film for room temperatures (well below disorientation temperature) was obtained from observations on the magnitude of the changes in the tangential force at the commencement of, and during, sliding with 'stick-slip' type action. Automatic recording² of thirty tangential force-time diagrams for the sliding surfaces was used as in earlier surface sliding work³, and the results processed to obtain the frequency polygon of all

changes in the tangential force, F_T . The magnitudes of the changes in F_T tended to be grouped around multiples of a definite value 'a', as indicated in the frequency polygon of Fig. 1. This could suggest that sliding can occur at definite strata-levels, and perhaps overturning of the molecules at these levels. Changes in the shearing strength of the film are registered as changes in F_T . In some, but not all, cases, there was micro-interferometric evidence of surface damage and this could not be correlated with the force measurements. It would seem that, although the changes in the shearing strength of any cold-welded metal asperities had contributed to the change in F_T , the final frequency polygon indicates that the changes were mainly due to different shearing strengths of the film at different levels, corresponding to integral multiples of the value at 'a'.

Fig. 1

It would seem that sliding had occurred at selected planes of slip (with overturning?) which exist by virtue of the molecular surface orientation forces; there would be a low probability of a slip occurring at a molecular plane very close to the metal surface where orientation forces are strongest, but the probability increases for molecular planes further removed from the surface.

LETTERS TO THE EDITORS

PHYSICS

Gas-Insulation of a Hot Plasma

THE attempts to heat a plasma to thermonuclear temperatures have all started from the idea that the plasma should be separated from the walls of the vessel by magnetic fields in vacuum. The purpose of this communication is to discuss another possibility, namely, to insulate the plasma from the walls by means of a magnetized gas at high pressure. As the thermal conductivity increases with temperature, a hot gas seems to be a poor insulator; but at high temperatures, where the gas becomes ionized, the thermal conductivity can be decreased very much by a magnetic field. Its variation with the temperature is shown qualitatively in Fig. 1. The first maximum is due to the dissociation and the second to ionization, whereas the third is produced by the electron conductivity and the fourth by the ion conductivity. At high temperature the ion conductivity dominates and its asymptotic temperature variation is as $T^{-5/2}$.

Fig. 1

If in a cylindrical vessel, $r = r_0$, filled with gas, a central region, $r = r_1 < r_0$, is heated with the power Q per unit length but the wall is kept at a low temperature, we have (neglecting radiation losses):

$$Q = -2\pi r \kappa \frac{dT}{dr} \quad (1)$$

$$Q = \frac{2\pi}{\ln(r_0/r_1)} \int_0^T \kappa dT \quad (2)$$

Because the integral $\int_0^T \kappa dT$ is finite, we can expect a 'burn-out', resulting in a very high central temperature if the power exceeds a certain value Q_b . As the largest part of the integral is due to the ion-gas contribution to κ , we can in an approximate calculation use the thermal conductivity of the ion gas only. This is according to Braginskii¹ (see also Rosenbluth²).

$$\kappa = \frac{3}{4\sqrt{\pi}} \frac{k(kT)^{5/2}}{\sqrt{m_i} e^4 \lambda} \frac{2.645 + 2(\omega_i \tau_i)^2}{0.677 + 2.70(\omega_i \tau_i)^2 + (\omega_i \tau_i)^4} \quad (3)$$

$$\text{where } \omega_i \tau_i = \frac{eH}{m_i c} \frac{3\sqrt{m_i} (kT)^{3/2}}{4\sqrt{\pi} \lambda e^4 n_i} \quad (4)$$

$$\text{If the pressure } p = nkT = 2n_i kT \quad (5)$$

is constant, (3) and (4) give for deuterium:

$$\kappa = KT^{5/2} \frac{1 + 0.756 (T/T_1)^5}{1 + 3.99 (T/T_1)^5 + 1.48 (T/T_1)^{10}} \quad (6)$$

$$\text{with } K = 0.53 \times 10^{-14} \text{ W. cm.}^{-1} \text{ deg.}^{-7/2} \quad (7)$$

$$T_1 = 4.0 \times 10^4 \left(\frac{p}{H} \right)^{2/5} \quad (8)$$

T_1 is approximately the temperature that corresponds to maximum ion conductivity.

Introducing the expressions 6-8 into 2, we can write the critical power as:

$$Q_b = \beta KT_1^{7/2} \quad (9)$$

$$\text{where } \beta = \frac{2\pi}{\ln(r_0/r_1)} \int_0^\infty \frac{x^{5/2} (1 + 0.756 x^5)}{1 + 3.99 x^5 + 1.48 x^{10}} dx \quad (10)$$

is a constant of order unity. If the ratio r_0/r_1 is of the order of 10, β is approximately 3. Putting $\beta = 3$, we get:

$$Q_b = 200 \left(\frac{p}{H} \right)^{1.4} \text{ W. cm.}^{-1} \quad (11)$$

If in a thermonuclear reactor we want $T = 2 \times 10^8$ degrees and $n = 10^{14} \text{ cm.}^{-3}$, the pressure should be $p = nkT \approx 3 \times 10^6 \text{ dynes/cm.}^2$. Then we find:

$$\begin{array}{ll} H = 10^4 \text{ gauss} & H = 10^5 \text{ gauss} \\ T_1 \approx 4 \times 10^5 \text{ degrees} & T_1 \approx 1.6 \times 10^5 \text{ degrees} \\ Q_b \approx 600 \text{ kW. cm.}^{-1} & Q_b \approx 24 \text{ kW. cm.}^{-1} \end{array}$$

In a thermonuclear reactor, according to this principle the gas may be heated by a high-pressure arc. Maecker³ reports for an arc in water vapour at atmospheric pressure that a temperature of 5×10^4 degrees is reached already with a current of 1,400 amp. The temperatures which, according to calculations, are necessary for a 'burn-out', are not very much higher.

In comparison with a vacuum-insulated plasma, the gas-insulated device may have some advantage: (1) it is not subject to the same types of instabilities—but possibly to other types; (2) it should be easy to produce a clean plasma, because the hot region is protected from wall dirt by a thick layer of gas at high pressure.

In order to study the behaviour of a high-density plasma surrounded by neutral gas, an experimental programme has been initiated. To avoid the influence of electrode surfaces an electrodeless discharge is used. In a preliminary experiment a circular discharge has been produced in helium at pressures varying from 1 up to 600 torr in a glass torus of 10 cm. diameter placed between two one-turn coils through which a condenser bank $C = 2 \mu F$, 30 kV. is discharged in a damped oscillation with a period of 4 μsec . Kerr cell photographs show that an electrodeless circular arc discharge takes place. The current starts in a very narrow channel, which expands as the current increases. Fig. 2 shows two

ζ of the escape layer above the level at which mixing stops is fixed by:

$$\zeta' = H \ln (\pi \sigma^2 Q + 1) \quad (3)$$

where H is the mean scale height in the region below the critical layer and down to the level at which diffusion sets in, and Q is the number of particles in a vertical column of unit cross-section between these two levels. The values of h , ρ , and n appearing in succeeding columns of Table 1 were obtained by interpolation with respect to altitude from the data of King-Hele and Walker. Apart from the effect of the assumptions on M , the standard deviation of the results is perhaps ± 20 per cent.

Table 1. PHYSICAL PARAMETERS OF THE ATMOSPHERE AT THE CRITICAL LEVEL

Time	ζ (km.)	h (km.)	ρ (gm./c.c.)	n (particle/c.c.)	T (° K.)
Day	670	180	6.6×10^{-16}	2.5×10^7	2,000
Night	480	61	1.4×10^{-15}	5.3×10^7	1,000

Since the observations of satellite orbits yield the scale height h directly, the corresponding absolute temperature T follows from:

$$T = Mgh/R \quad (4)$$

where R is the gas constant and g is the gravitational acceleration. Curves of T for day and night conditions are shown as a function of altitude in Fig. 1, as determined under the stated assumptions on M from the data of King-Hele and Walker. These authors quote values for the temperature somewhat higher than correspond to the curves of Fig. 1, since the inverse-square variation of g in equation (4) was taken into account in the present work. The last column of Table 1 shows values of the absolute temperature T at the escape-level for day and night conditions. As a check on the figures, one can note my result⁶ that the pressure p at the critical level is simply the mean weight of a molecule distributed over the mean collision area, or:

$$p = (M/N)g (\pi \sigma^2)^{-1} \quad (5)$$

which is independent of temperature. On the other hand, p is given also by

$$p = (n/N)RT \quad (6)$$

for an ideal gas. The figures of Table 1 yield approximately the same result for p of equation (6) for the two cases of day and night conditions, and the average value $p = 7.1 \times 10^{-13}$ bar is closely that given by equation (5).

In general, the values of ζ in Table 1 exceed estimates made previously; Urey² assumed a range of 300–525 km. depending on the exosphere temperature, while Nicolet¹ obtained 450 km. from a model atmosphere. Both day and night values of the temperature at the critical level are considerably less than the value (of the order of 3,000° K. or higher) inferred by Nicolet⁷ and Urey² to account for the dissipation of helium-4 from the Earth's atmosphere. Spitzer⁴ gives a lower value (1,500° K.), but I have shown⁶ that the difference arises from his employment of superseded data in computing the lifetime of helium-4; when his computations are corrected by use of Johnson's revision⁸ of the data of the Rocket Panel, no significant difference from the results of Nicolet and Urey appears.

The quoted values of the temperature of the escape layer as inferred from the loss of helium-4

presuppose a steady rate of dissipation. The discrepancy (of some 1,000° K. or more) from the values of Table 1 may arise because the dissipation is in fact intermittent, as first suggested by Spitzer. Certainly, the general conclusions obtained from observations of satellite orbits are in harmony with this suggestion, since they imply that solar disturbances (yielding corpuscular radiation, ultra-violet rays, and soft X-rays) largely control the variations of short term in the atmospheric density at moderate heights (200–300 km.)^{9–12}. By virtue of equation (3), such variations must be reflected in the height and consequently in the temperature of the escape layer. Accordingly, it is possible that transient solar disturbances of duration too short to be revealed by the satellite observations (lasting for times less than perhaps 10 satellite revolutions) may play a dominant part in the dissipation of helium-4 from the terrestrial atmosphere.

One suspects that more refined data would show a variation with time of day, season of year, and latitude in addition to the gross variation from day to night exhibited by Table 1. Thus, no one set of physical parameters of the escape layer can be universally valid.

Stress Effects on Thermoremanent Magnetization

It has recently been reported^{1,2} that the effect of stress on a rock acquiring a thermoremanent moment is completely reversible. Experiments carried out here have shown this is not true for all rocks. Tests have been made on a number of rocks containing different minerals, and in every case a rotation of moment induced by pressure, together with a reduction of moment, has been observed.

Uniaxial stress experiments were carried out using a non-magnetic pressure vessel designed by one of us (R. N. N.). This consists of a thick-walled hollow dural cylinder with a lid of the same material. Pressure is applied by means of a cylindrical nimonic piston, which compresses a cubical rock specimen against a nimonic cylinder attached to the inside of the lid of the pressure vessel. The rock specimen is heated to its Curie point by means of an a.c. current passing through a nichrome wire element embedded in a fire cement annulus which fits closely around the specimen. The current through this heater is switched off while the specimen is cooling in a magnetizing field of 1.5 oersted supplied by a Helmholtz coil system.

The apparatus is capable of heating a specimen to 600° C. and cooling it again to room temperature in a period of about 2 hr., while a hydraulic system allows constant pressures between zero and 1,500 kgm./cm.² to be obtained.

Experiments with a particular pressure and field direction were carried out on groups of four specimens. Each specimen was heated four times in all, the sequence being the first and third heatings without pressure, and the second and fourth with pressure. All measurements of inclination and intensity of moment were made using a spinning magnetometer² which was modified to be capable of consistently detecting angular differences of 0.3°.

A very detailed study has been carried out on material obtained from a Tertiary dolerite dyke in Skye, Scotland. Initial experiments on material from this dyke showed that the application of uniaxial pressure during the acquisition of a thermoremanent moment caused a rotation of the moment away from the stress axis, together with a reduction in the intensity of the moment. Further experiments were made on the dyke material, which, after one heating, was shown to contain a pure magnetite and an impure maghemite, and the variation of the angular rotation of moment with the following parameters was examined: (i) pressure; (ii) the angle, θ , between the magnetizing field and the pressure axis; (iii) the intensity of the magnetizing field; (iv) the grain size of the magnetic constituents of the rock (composition remaining constant).

All the experiments carried out showed clearly that the application of pressure during magnetization produced a measurable effect. It was found that the observed rotation of moment was dependent on (i), (ii) and (iv), but was apparently independent of the intensity of the magnetizing field in the range 0.5–3.0 oersted. Figs. 1–3 show the results of these investigations.

Further positive experiments have been carried out on rocks containing pyrrhotite, an ilmenite-haematite solid solution and a magnetite-ilmenite solid solution. In addition, shear stress has been shown to produce a measurable rotation of moment.

Angle θ between magnetizing field and pressure axis

Fig. 1. Dolerite dyke centre material (100 μ magnetite grain diameter). Pressure, 550 kgm./cm.², H , 1.5 o.

Fig. 2. Dolerite dyke centre material. θ , 45°; H , 1.5 o.

Fig. 3. Dolerite dyke centre and contact material. H , 1.5 o.; θ , 45°; pressure, 880 kgm./cm.²

In general, the mechanism of the pressure effects described appears to be complex. In the absence of measurements of various relevant parameters in the region near the Curie point where the greater part of the moment is acquired, no quantitative relationship between magnetostriction, etc., and the observed pressure effects can be seen. However, the variation of the thermoremanent moment of this dyke material with pressure is not irreconcilable with the known magnetostrictive properties of magnetite reported for room temperatures⁴ if it is assumed that magnetostriction decreases regularly to a zero value at the Curie point.

There is a close similarity between the variation of rotation of moment with grain size and the reported variation of coercive force with grain size⁵. It has been suggested that the latter variation results from a change in the mechanism of magnetization, and, if this is so, it is obviously an important factor in the production of angular pressure effects.

It has been found during our experiments that each specimen has a slight intrinsic anisotropy which may cause it to acquire on successive non-pressure heatings

PROSPECTS OF SCIENTIFIC AND TECHNOLOGICAL ADVANCEMENT

Science and Resources

Prospects and Implications of Technological Advance. Edited by Henry Jarrett. Pp. xiii+250. (Baltimore, Md.: The Johns Hopkins Press; London: Oxford University Press, 1959. Published for Resources for the Future, Inc.) 40s. net.

THIS is a most unusual kind of book even although it is a collection of essays. It is the result of a plan by Resources for the Future Incorporated. This is an organization in the United States the job of which it is as a non-profit-making organization to look to the future in the field of research and education so far as it affects the development, conservation and use of natural resources.

The book as a whole provides a look into the future in a number of directions. It originated as a series of lectures which were arranged in a rather original sort of way. First, a leading scientist was invited in his own particular field to give his ideas and views as to future developments and requirements in that field. Naturally, the extent to which the lecturer could look into the future depended very much on the subject under discussion. Secondly, two non-scientific commentators were then invited to discuss and examine the first lecture and to put their points of view forward almost as an informed lay person would do. This gives unusual character to the book and makes it especially profitable in that it can be read by scientists and non-scientists alike. Those familiar with the fields under discussion may no doubt disagree with some of the predictions, for that is inevitable; but the purpose of the book is undoubtedly to stimulate thoughts on problems which affect almost every country. Even although speculation is difficult, there is every reason to engage in it so that even in the immediate future misuse and waste of natural resources may be avoided and that those that are known to exist are utilized to the best possible advantage.

The list of authors of the introductory lectures demonstrates at once that the book is absolutely authoritative: "Genetics", by J. W. Beadle; "Weather Modification", by H. R. Byres; "Exploring for Minerals", by J. A. S. Adams; "Chemical Technology", by E. P. Stevenson; "Nuclear Energy", by W. F. Libby; "New Knowledge from Outer Space", by L. A. DuBridge.

The commentators of these essays come from a wide range of professional disciplines and even from politics. This gives a very stimulating series of additional articles often with a very clearly defined personal point of view but none the less interesting in spite of that. It is clear that the editor has not wielded his pen too strongly and has allowed the

authors to give free rein to their thoughts and opinions. This may make the treatment of the topics in the book somewhat uneven; but this is not a text-book or a monograph but eighteen essays devoted to the problems of the future in the fields covered.
H. W. MELVILLE

MAN AND HIS ANCESTORS

Mankind in the Making

The Story of Human Evolution. By Dr. William Howells. Pp. 382+8 plates. (Garden City, New York: Doubleday and Company, Inc., 1959.) 4.95 dollars.

An Introduction to Physical Anthropology

By Prof. M. F. Ashley Montagu. Third edition. Pp. xvi+771. (Springfield, Ill.: Charles C. Thomas; Oxford: Blackwell Scientific Publications 1960.) 116s.

DR. HOWELLS has set himself the task of giving a full and detailed account of our knowledge of human evolution, and of telling the story in an informal and light-hearted style. The result is something of a clash between instruction and entertainment. The theme is interlarded with whimsicalities and with technicalities smoothed over by a jocular familiarity ("Man, the hero of the tale" . . . "Proconsul . . . bless his heart!" "Miss Middle Pleistocene" and "Fräulein Steinheim") all done with the best pedagogic intentions. That this exercise in popular writing may not be to everyone's taste should not be allowed to detract from the soundness and competence of Howells's interpretation. The evidence is well marshalled, controversies of the past and present are fairly presented and his judgments appear consistently reasonable. This is particularly evident in his treatment of the rather complex problem of the specific and subspecific relations within the genus *Homo*, involving the allocation of fossil specimens of a diversity ranging from the late but 'fully' Neanderthaloid to the early but more *sapiens*-like varieties, notably Swanscombe man. His handling of the still-vexed problem of *Oreopithecus* (which he regards as a primitive hominoid possibly near the hominid stem) is judicious. So also is his analysis of the status of *Australopithecus* and of *Afhanthropus*. The latter he sees as related to Peking and Java man, but unworthy of a generic status. The evolutionary chapters are preceded by informative sketches of the living primates and of their vertebrate and mammalian background. Dr. Howells concludes with a description of present-day races which is rather disappointing. There is no serious attempt to utilize the great body of available genetic data in an analysis of the dynamics of human

polytypy as evidenced in the operation of, for example, isolation, mixing and selection as factors responsible for the observed distribution of anthropological characters.

Prof. Ashley Montagu's text-book, in its enlarged and revised third edition, represents a serious endeavour to put the student in touch with many of those issues which Dr. Howells allows to slip by.

Thus after the first chapters (in which a sufficient abundance of the taxonomic and morphological facts of primatology and palaeoanthropology are provided) there is an interesting dissertation on the possible evolutionary processes underlying the genesis of the Hominidae and modern man, and particularly on 'neoteny' as a major factor. There follows a chapter of conventional classification and categorization of human racial stocks—an exercise which Montagu, justifiably, finds too limited and arbitrary. He places much more emphasis on the evidence of blood groups and other genetically understood characters as indicators of group affinities.

This section is well documented (though many of the text figure references are not to be found in the bibliography). Population (or as he prefers 'ethnic') differentiation is next considered in relation to mutation, isolation and selective agencies of various kinds—climatic, social, sexual and disease. The interaction of heredity and environment, the usefulness and limitation of the twin method, the determinants of 'constitutional' variation, and a chapter on body composition (by Prof. Brožek) all make up useful sections. An appendix contains an over-compressed guide to techniques of use in physical anthropology.

The book has its merits, but the material is presented in a disconcertingly uneven fashion. In some sections very detailed tables are given with only the slightest relevance to the text, yet the long arguments on 'race' and 'ethnic' differentiation consist in large part of generalities scarcely reinforced by specific evidence. The student could be better served by detailed and quantitative illustration and analysis of, for example, balanced polymorphism, gene-flow between hybridizing populations, mutation-rates or genetic drift. Even the calculation of gene frequencies is dealt with in a somewhat perfunctory way.

There are a number of obvious lapses which careful revision of the manuscript should have put right. For example, in Fig. 44, *Australopithecus* is shown as the crown of the Pongid family whereas in the text (for example, p. 288) its hominid status and particularly that of *Zinjanthropus* is repeatedly conceded. In the same figure the semi-mythical *Africanthropus* is included while Rhodesian man is omitted. There is confusion between orthogenetic and ortholinear evolution (p. 157). The 'early' Kafuan stone industry has for some time been regarded as inadmissible. In matters of dating, the Pleistocene stages are not clearly defined and the Villafranchian, so important for the beginnings of the hominids, is left unexplained. The measurement of human skin colour by reflectance spectrophotometry, the only objective and reliable method, receives no mention in the section on methods.

Despite its blemishes and unevenness, Montagu's is a serviceable text-book; it has the paramount virtue of displaying clearly the full scope of physical anthropology and of conveying in a stimulating way the live issues of the subject.

J. S. WEINER

THE CENTRAL NERVOUS SYSTEM

Evolution of Nervous Control from Primitive Organisms to Man

A Symposium organized by the Section on Medical Sciences of the American Association for the Advancement of Science, and presented at the New York Meeting on December 29–30, 1956. Edited by Allan D. Bass. Pp. vii+231. (Washington, D.C.: American Association for the Advancement of Science; London: Bailey Bros. and Swinfen, Ltd., 1959.) 52s.

THE title of this symposium is somewhat misleading though this need in no way detract from the value of an excellent collection of monographs contained in the book. The papers here presented do indeed represent, as Mr. Brodie claims, a variety of points of view, written as they are by a botanist, an embryologist, a neurologist, a physiologist, a psychologist and a psychiatrist; but, with the exception of a sketchy contribution by E. W. Sinott on "A Common Basis for Development and Behaviour in Organisms", they contain practically nothing that deals specifically with any theory of evolutionary development of nervous control. They provide, on the other hand, in the main an excellent phenomenological study of the physiological activity of the central nervous system, and there is no evidence that the various contributors envisaged any other purpose.

A highly suggestive note is struck by M. C. Niu in his chapter on chemical inducers. It must be regretfully noted, however, that so far as the nervous system is concerned there is as yet not a single observation that can be said to point to the occurrence of any such inductive process, whether attributable to ribonucleic acid or other body in either the production of mutations or the control of normal development.

The essay by Niu has undoubtedly enhanced the value of the book by reminding neurophysiologists of the important part that may possibly be played by chemical induction, but as yet it remains a possibility only. It is a possibility that can only be fruitful if specificity of inductor elements somewhat in the form of Iscovesco's specific organ inducers should, after all, prove to be a reality. C. I. Prosser suggests that the primitive electrical response of excitable tissue may be of the local graded sort rather than all or none propagated impulses. Together with some analogous speculations contained in the same essay it must very reluctantly be admitted that methods and apparatus for their verification are not yet in sight. H. Grundfest in his contribution entitled "The Evolution of Conduction" gives an excellent critical review of our knowledge of bio-electrogenesis in the nervous system. Defining an excitable cell as one capable of responding to a stimulus by electrogenesis, he distinguishes as distinct functions: the grading in proportion to the strength of the stimulus, and maintained so long as the stimulus lasts, which can be of two types, depolarizing and hyperpolarizing, each of which is produced by a specific transducer action of the electrogenic membrane; and a second generalized function due to the electrically excitable spike generating cell mechanism which can be activated by depolarizing electrical activity of the input and is adapted to conducting a coded message. Grundfest acknowledges that we have as yet no knowledge as to the means by which conducted messages are capable of

releasing specific excitants for the input of the next postjunction cell.

The essay by G. S. Koelle on neurohumoral agents, while giving an excellent account of the present state of our knowledge of the part played by such agents on synaptic transmission, would be enhanced by fuller reference to such facts as are known with reference to the all-important subject of the specific action of local hormones on the central nervous system. J. V. Brady, on the effect of drugs on animal behaviour, has made a gallant attempt to develop an animal laboratory approach to behaviour problems in neuropsychiatry. The urgent need for appreciation of the basic situation of the organism, both as regards the internal and external environment during and preceding any pharmacological experiment, here receives attention which is only too often absent in the evaluation of the neuropharmacological activity of various substances.

The review of brain chemistry by Irvine H. Page is somewhat too ambitious for the twenty pages allotted to it. H. J. Teuber gives his views on alterations of behaviour after brain injury. One could wish that he showed some greater appreciation of the existence of two major difficulties that tend to vitiate the conclusions that psychologists are prone to arrive at in their evaluation of behaviour changes after trauma. First, that anatomical and functional disturbance in the vicinity of the lesion is apt to be of far greater extent than its localization might suggest, and secondly, that the cerebral system is capable of very great lability in its power of compensating lost functions. Further, that without a preliminary knowledge of the pretraumatic mode of function in any given case, such as the habitual type of imagery, assessment of behaviour becomes a matter of utmost difficulty. The essay of I. A. Mirsky on psychoanalysis and human behaviour is obviously out of place in a book of this nature which is not addressed to the clinical psychiatrist.

The volume may be recommended as containing a number of interesting papers, but would certainly benefit greatly if the various contributors had been afforded more space and worked to a more definite scheme of co-operation.

F. GOLLA

ANTIBIOTICS REVIEWED

Antibiotics Annual, 1958-1959

Pp. vii + 1107. (New York: Medical Encyclopedia, Inc.; London: Interscience Publishers, Ltd., 1959.) 90s.

Antibiotics Annual, 1959-1960

Pp. xvii + 1034. (New York: Antibiotica, Inc.; London: Interscience Publishers, Ltd., 1960.) 15 dollars. Both volumes edited by Dr. Henry Welch and Dr. Felix Marti-Ibañez.

THE 1958-1959 and 1959-1960 volumes of "Antibiotics Annual" are really an account of the proceedings of the sixth and seventh annual symposia on "Antibiotics", and follow on the whole the pattern established by their predecessors. Both are enormous volumes of more than a thousand pages; both cover almost every conceivable aspect of the antibiotics, and there is a wide variation in standard and in the style of the papers presented.

In the first volume, after opening remarks by Dr. H. Welch and Dr. F. Marti-Ibañez, Sir Howard Florey deals with penicillin in perspective, a paper

all the more interesting in view of recent work on synthetic penicillins, some aspects of which are dealt with in the second volume. This article is followed by Dr. S. A. Waksman on the antibiotics of actinomycetes, by Dr. C. S. Keefer on the impact of antibiotics on medicine in the United States, and by Dr. H. F. Dowling on the history of the broad-spectrum antibiotics. The more-detailed papers which follow deal with some long-acting sulphonamides, nitrofurans, phenoxymethyl penicillin (penicillin V), spiramycin, new uses and forms of administration of tetracyclines, oleandomycin and triacetyloleandomycin, tetracycline and oleandomycin combinations, erythromycin propionate, novobiocin, ristocetin (spontin), actinobolin (a new broad-spectrum antibiotic showing some effect against experimental tumours and mouse leukaemias), streptovivacin (another 'anti-tumour' antibiotic), vancomycin, kanamycin and others (this list does not include a number of single articles dealing with isolated topics). The later part of the volume deals mainly with technical methods, such as standardization of antibiotic sensitivity disks and other methods of determining antibiotic sensitivities, epidemiological investigations of the frequency of staphylococci of various types in various communities, and finally some experimental work on the growth-promoting effects of antibiotics in animals.

The volume closes with two panel discussions, first on the current status of erythromycin and kanamycin, novobiocin, oleandomycin, ristocetin and vancomycin, with particular reference to their use in staphylococcal disease, and secondly the causation, prevention and control of staphylococcal disease in hospitals.

In the second volume, again following introductory remarks by Dr. Welch and Dr. Ibañez, there are general articles on the challenge of new drugs to the pharmaceutical industry, to the clinical investigator, to the food and drug administration and to the practising physician. Some of the subjects covered in the special articles are phenoxymethyl penicillin (known as 'Broxil' in the United Kingdom and as 'Synocillin' in the United States), some papers on the effect of various substances on the inhibition of penicillinase in staphylococci, then a series of papers on some new antibiotics with increasingly outlandish names—aspertocin, fervenulin, streptozotocin, rifomycin, paromomycin, and so on. A good many papers are devoted to tetracycline analogues, including the new demethylchlortetracycline. The relative merits of the four tetracyclines are dealt with in one of the few papers from Britain by Prof. L. P. Garrod and Dr. Pamela M. Waterworth, as is the use of injectable tetracycline preparations and the treatment of gonococcal infections by Dr. R. R. Willcox. There are several articles on the incidence of reactions to penicillin and a series of papers on laboratory techniques and methods of testing antibiotic sensitivities. Several papers deal with the anti-fungal antibiotic, griseofulvin, and there is a collection of papers giving clinical and epidemiological investigation of the effects of different antibiotics and antibiotic combinations in a variety of infections.

The second volume ends with two panel discussions, one on the present status and problems involved in human sensitization to antibiotics, and one on the chemotherapy of acute and chronic paediatric and geriatric infections.

The contents of both volumes are arranged in a rather haphazard way, and it is not always possible

to discern any logical sequence of papers except where a group of papers deals with one antibiotic.

Undoubtedly the most interesting papers in either of these two volumes are those dealing with the new synthetic penicillins. Hints are given of new penicillins to come and it is to be hoped that the next volume will give some interesting information about further developments in this field. R. KNOX

BIOCHEMICAL RESPONSE TO INJURY

The Biochemical Response to Injury

Edited by H. B. Stoner, with the assistance of C. J. Threlfall. (A Symposium organized by the Council for International Organizations of Medical Sciences, established under the joint auspices of Unesco and WHO.) Pp. xi+467. (Oxford: Blackwell Scientific Publications; Springfield, Ill.: Charles C. Thomas, 1960.) 57s. 6d.

THE proceedings of this symposium will be of interest to others besides those concerned practically with the effects of injury and the indefinable syndrome of shock. The book contains seventeen papers which between them consider the effects, measured in a variety of ways, of almost all forms of trauma except irradiation. Each paper gives a comprehensive account of the research of the particular author and of related work by others, so that, with a bibliography of a thousand references with titles and an adequate index, the book is most informative on the tenor and outcome of work over the past decade. Its value is enhanced by a well-edited report of the discussions including a thoughtful account of the strategy, tactics and integration of future work which may be particularly recommended to those who contemplate such work.

Though primarily there may be a specific biochemical lesion, and consequently many inter-related changes at a biochemical level, the response of the animal to injury is a complicated physiological affair in which the nature and extent of biochemical effects is dependent on the constitution of the animal. It is therefore extremely difficult to gauge the significance of any particular biochemical change, and the participants in the symposium were agreed that few general conclusions can yet be drawn. The effect of injury on the vascular system is the core of the problem, but though from time to time a particular substance affecting capillary permeability has been incriminated, it is clear that no single mediator can sustain the role of prime villain in the development of shock. Moreover, the divergence of response to similar injuries in different species complicates the assessment of the general validity of conclusions drawn from certain animal experiments, for example, the importance of the absorption of bacterial endotoxins from the gut in haemorrhagic shock.

The human response to injury, however, seems to be dominated by an effect on renal function which is rarely apparent in experimental animals, and many of the chapters are of particular interest and importance to clinicians. These include accounts of the disturbance in protein metabolism (Cuthbertson), in water retention and electrolyte loss (Wynn) and in the pituitary-adrenocortical system (Pekkarinen) after surgical trauma or physical injury, the clinical trial of saline therapy (Rosenthal), rouleaux formation

(Fahraeus), and the effect of limb ischaemia on adrenal secretion and body temperature (Stonor and Threlfall).

Other chapters in which the lesions in structure or function produced by specific substances are explored, offer a stimulating challenge to the experimental pathologist, the cytologist and the biochemist; they include the effects of histamine and other endogenous substances (Miles and Wilhelm) and of bacterial toxins (Smith) on vascular permeability, and the early effects of toxic chemicals on mitochondrial structure and function (Fonnesu). The interpretation of these phenomena is still too often handicapped by our ignorance of the physico-chemical nature and interplay of the cell structures involved in the injury, and it is to be hoped that the problems poised in this book will promote further attack in this fundamental field. M. G. MACFARLANE

PHYSIOLOGICAL CARCINOLOGY

The Physiology of Crustacea

Edited by Talbot H. Waterman. Vol. 1: Metabolism and Growth. Pp. xvii+670. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 22 dollars.

THIS is the first of two volumes which are intended to give a general survey of our present knowledge of the physiology of Crustacea. There are seventeen chapters, the first of which is an introduction to crustacean biology. This chapter seems to have suffered from over-compression, and contains some curious suggestions regarding the evolutionary relationships of the various crustacean sub-groups. For example, it is suggested that the Ostracoda and Conchostraca have a common origin, without giving any reasons. This is a difficult suggestion for anyone familiar with the two groups to accept, or to understand why it should be made. To offer it, unsupported, to the physiologist looking for an introductory account of the probable evolutionary relationships of crustaceans can only be misleading.

The remaining sixteen chapters deal with a variety of topics, ranging from respiration, circulation and heart function to autotomy and regeneration. These chapters are all written by separate authors, and the book reflects the advantages and disadvantages of such a system. The great advantage is that one gets a variety of outlooks, and each chapter is written by an expert who has contributed original work to the particular field. Most of the chapters not only present useful summaries, but also make suggestions as to where there is need for further work, and where new advances might be expected to be made. The main disadvantage lies in the lack of the rounded overall view that one gets from a single author; but the time has passed when one person could be expected to be equally well informed on the variety of topics covered in this book.

The problems of nomenclature and synonymy have been dealt with very sensibly by providing a systematic index which includes synonyms. This allows the consistent use of one name throughout the text while retaining the possibility of referring back to original accounts which used an older name. As a further aid, particularly to the more advanced worker, each chapter is followed by about a hundred (some by more than two hundred) references, so that apart from

providing a great deal of information this book also provides a detailed guide to the original literature.

Anyone interested in the Crustacea as experimental animals will find this book indispensable, and there is much in it that the ecologist too can benefit from reading.

J. GREEN

DIDACTIC PLANT PHYSIOLOGY

Pflanzenphysiologie

Von Prof. Henrik Lundegårdh. Pp. xv+717. (Jena: Gustav Fischer Verlag, 1960.) 48.70 D.M.

NOBODY having the least acquaintance with Prof. Lundegårdh, either personally or through his published work alone, will expect any book written by him to be tamely conventional. It is perhaps proper therefore to make it clear at the start that, although highly individual, this still sets out to be a general text-book and succeeds. Moreover it attempts, what is admittedly one of the most desirable and yet most difficult achievements in didactic plant physiology, its comprehensive treatment from a single pen. It is characteristic of the author that no concessions whatever have been made to the difficulties he has challenged either by limiting their scope or by shirking them as they arise. On the contrary, the book's limits have been set even wider than might be considered essential; there is, for example, a much fuller treatment of the straight anatomy of the higher plants than is generally considered needful in the context. Less surprisingly, though equally important, the roots of metabolic physiology in chemistry and enzymology receive fully adequate treatment; and the frontiers of physiology with genetics are not forgotten, nor those ecological connexions through which Prof. Lundegårdh himself made his first approaches to physiology.

His unfolding of the subject follows natural lines, proceeding from the organization of the cell and the general properties of protoplasm, through metabolism, nutrition and water balance, to growth and plant movement.

Prof. Lundegårdh has himself made important contributions in many of these fields during the course of his long and distinguished career as a research botanist, and the fact is not hidden from the reader. His adventurous mind has led plant physiologists along more than one exciting trail during the past generation, and this book is sure to make a striking impact on the minds of those students into whose hands it comes. They must surely be stimulated, if they have it in them, to creative thought on their own account. When Prof. Lundegårdh states a case you are left in no doubt about the nature of the problem or his own personal solution of it. You may be stimulated to more or less violent disagreement; but, even if you are of one mind with the author, you are very likely to feel that the matter has been illuminated for you from a new angle. It is probably not possible to write an account of the present state of plant physiology which would satisfy all, or even most, specialists and, if it were, the result would inevitably be much duller than the book Prof. Lundegårdh has written. It appeared first in 1950 in the Swedish language and the version now published in German has been considerably enlarged and partially rewritten. It would be pleasant if it were possible to think that in the next few years an English edition would also be

appearing so that it might exercise its influence on the undergraduates of our own botany departments.

W. O. JAMES

BACTERIOLOGY OF THE MOUTH

The Microbial Flora of the Mouth

By Dr. K. A. Bisset and Dr. G. H. G. Davis. Pp. 100+8 plates. (London: Heywood and Co., Ltd., 1960.) 22s. 6d. net.

THE normal oral cavity supports a very large and varied population of bacteria, fungi and protozoa. These organisms appear shortly after birth, being derived in the first instance from the maternal genital tract and later from the air, clothes, feeding utensils and other environmental objects, and persons, that come into contact with the infant. This microbial flora remains throughout life, undergoing changes that are probably mainly quantitative in the presence of oral infection. Apart from lesions due to specific micro-organisms, such as syphilis or tuberculosis, most infective conditions of the mouth, including the commonest of all, dental caries, are due to, or associated with, the organisms that are normally present. For this and other reasons the role in pathogenesis of the oral flora is not easy to clarify, and much more work on this aspect of oral disease requires to be done. A first essential, of course, is an accurate knowledge of the characteristics of the normal flora and a more or less agreed taxonomy and classification. It is indeed remarkable that such has not yet been achieved, for even the earliest bacteriologists had directed their attention to the organisms of the mouth. No doubt the fact that oral infections are rarely life-destroying has accounted for the lack of sustained interest in this field.

This short book is a very welcome contribution to the study of oral bacterial disease, for it is a succinct account of the oral flora from a systematic point of view, and it gives valuable practical advice. Though it is offered by the authors to dental, medical and bacteriological students as well as to their teachers and to research workers, it is unlikely that it will prove of great interest to undergraduates. Teachers and investigators, however, will find it of considerable value, perhaps not least for the practical information given in the appendixes that follow most of the chapters. There, detailed information on the composition and use of media and on various procedures for isolation is given, with appropriate references to the literature. Information of this sort is not readily available in collected form elsewhere.

R. B. LUCAS

MICROBIAL GENETICS

Microbial Genetics

Tenth Symposium of the Society for General Microbiology held at the Royal Institution, London, April 1960. Edited by W. Hayes and R. C. Clowes. Pp. x+300. (London: Cambridge University Press, 1960. Published for the Society for General Microbiology.) 42s. net.

THIS is the first time that a symposium of the Society for General Microbiology has taken the genetics of micro-organisms as its theme. This cautious treading is easy to understand. Microbial

genetics, at present the most rapidly advancing frontier in microbiology, and already crowned by Nobel prizes, practically did not exist before 1940. In twenty years it has leaped by a series of major steps: the techniques for the isolation and use of nutritional mutants in 1940; the identification of deoxyribonucleic acid as the substance responsible for transformation in *Pneumococcus* in 1944; gene recombination in bacteria and in bacterial viruses in 1946; bacteriophage-mediated transduction in 1952; 'parasexuality' in fungi in 1953; unidirectional and partial transfer of genetic material in bacteria in 1953, and many others later.

All these advances have made it clear that micro-organisms present such a variety of processes of genetic recombination that higher organisms seem dull in comparison.

While making possible this spectacular progress in the knowledge of micro-organisms themselves, microbial genetics has opened, and contributed decisively to, the general field of molecular genetics, that is, the description of the processes of heredity and variation at the molecular level. This was the consequence of two main reasons: the enormously increased resolving power of genetic analysis when in one experiment millions, rather than hundreds, of individuals can be handled, and the ease with which chemical techniques can be used with micro-organisms.

This volume, for which the Society and the editors, Drs. Hayes and Clowes, should be congratulated, is the collection of thirteen papers and an introduction presented at the symposium. The standard is very high almost throughout and most of the papers are also presented in an intelligible form. The contributors include some of the best people in the various sections of the subject. It is a volume that no microbiologist can ignore and that all geneticists—especially those without direct acquaintance with microbial genetics—will profit by reading.

[G. PONTECORVO

1942, Dr. A. Schierbeek has been editor-in-chief of this undertaking. In 1950, he published in Dutch a two-volume work on Leeuwenhoek, to which he has now added the present book in the English language. It opens with a valuable biographical chapter by Dr. Maria Rooseboom, who tells us much about the social history of the Netherlands in Leeuwenhoek's day. She makes the point that Leeuwenhoek was first introduced to the Royal Society of London at a time when the two countries were at war.

We are here given a view of the father of microscopy in the round. It would be hard to over-estimate the importance of the service to science which these authors have rendered. Here is a book which all biologists must read, and which every student of the history of the sciences will need to study. One of the most interesting topics which are discussed is Leeuwenhoek's relations with the Royal Society. Though he never met them, these men were his colleagues. Their confirmation in 1677, after repeated trials, of the presence of animalcules in 'pepper water' is a vivid chapter in the history of science. Only fourteen years later, however, Robert Hooke lamented that Leeuwenhoek already stood alone in the use of the microscope. Yet for a further thirty years the Society continued to receive the letters from Delft.

Dr. Schierbeek's book is accompanied by a number of plates reproduced mainly from the original publications of Leeuwenhoek. I would suggest that in further editions the references should be given to the year and page in the *Philosophical Transactions*.

ARTHUR HUGHES

APPLIED MICROBIOLOGY

Advances In Applied Microbiology

Vol. 2. Edited by Wayne W. Umbreit. Pp. xii + 384. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 12 dollars.

ON the whole, the second volume in this series fulfils the promise of the first. The book contains eight fairly comprehensive reviews and eight short articles that were presented during a symposium on "Engineering Advances in Fermentation Practice" before the Division of Agricultural and Food Chemistry at the American Chemical Society meetings in September 1959. Five of the reviews are concerned with the use of micro-organisms in fermentation processes: recent work on the oxidative fermentation of industrial wastes, with particular reference to the disposal of dairy waste, is discussed in a posthumous article by N. Porges; G. J. Haas points out the importance of microbial control during brewing, and details the methods used during the brewing of lager beer; R. J. Allgeier and F. M. Hildebrandt describe the development of the use of deep-fermentation equipment for the manufacture of vinegar; T. H. Soudt contributes an account of the transformations of steroids that can be accomplished with micro-organisms—such interconversions are important adjuncts to chemical synthesis; and W. J. Oswald and C. G. Golueke give an interesting, though at present somewhat hypothetical, discussion of the possibility of biologically transforming solar energy into electrical power. Two reviews deal with the collection and counting of micro-organisms: H. W. Batchelor considers the techniques available for

THE FATHER OF MICROSCOPY

Measuring the Invisible World

The Life and Works of Antoni van Leeuwenhoek, F.R.S. By Dr. A. Schierbeek. With a biographical chapter by Dr. Maria Rooseboom. (The Life of Science Library, Vol. 37.) Pp. 223 (28 plates). (London and New York: Abelard-Schuman, Ltd., 1959.) 25s. net.

ANTONY VAN LEEUWENHOEK is the most astonishing figure in the history of biology. Unaided, he discovered bacteria, described spermatozoa, and observed a nucleus in a blood-corpuscle. Not for more than 150 years was progress in microscopy resumed at the resolution which Leeuwenhoek could command with his home-made lenses. His discoveries extended over fifty years and were described in a series of some 165 letters to the Royal Society. The last, in 1723, was dictated from his death-bed.

Yet our knowledge of this amazing man has remained strangely incomplete until the present time. Some thirty years ago, a committee of Dutch scientists began the task of assembling a series of volumes in which each of Leeuwenhoek's letters is followed by

dern description of the objects concerned. Since

collecting and measuring particulate matter suspended in air, and R. Ehrlich discusses the properties and applications of membrane filters. In the remaining article, F. Kavanagh contributes a thoughtful essay on the theory, practice and pitfalls of microbiological assays.

As in the first volume, the wide variety of topics covered illustrates the broad scope of the applications of microbiology, but it is perhaps unfortunate that much of the international flavour so desirable in publications of this type has been lost. All the authors are drawn from laboratories in the United States, and several of the chapters, although giving full credit to work done outside the United States, are frankly concerned primarily with American practice in the field discussed.

J. W. G. PORTER

OYSTERS: THEIR BIOLOGY AND GASTRONOMY

The Glorious Oyster

Edited by Hector Bolitho. Pp. 174+17 plates. (London: Sidgwick and Jackson, Ltd., 1960.) 25s. net.

Oysters

By Prof. C. M. Yonge. (New Naturalist Special Volume.) Pp. xiv+209+17 plates. (London: William Collins, Sons and Co., Ltd., 1960.) 21s. net.

THESE two books provide an interesting contrast. Hector Bolitho is frankly concerned with the pleasures of oyster eating and is supported by W. A. Bentley, in whose restaurant he has no doubt extended his practical experience. Maurice Burton contributes chapters on reproduction and growth, enemies, anatomy and physiology and culture. C. M. Yonge, however, sets out to provide an up-to-date, fully illustrated, scientific account of the structure, biology and cultivation of the European oyster, but includes also references to similar work on other species from the United States, Japan and Australia.

"The Glorious Oyster" first appeared in 1929 but became out of print. This revised and extended edition is well presented and is illustrated by photographs of still-life paintings from collections in Europe and the United States. Some of these, as, for example, that by Jan Steen, which also appears as a frontispiece in Prof. Yonge's book, are well known, but others, such as those by Braque and Manet from private collections, are unfamiliar but very appropriate.

In the section on the history of the oyster, Hector Bolitho has clearly drawn his information mainly from Philpots's monumental work of 1890, and this is acknowledged. The description of oyster dredging at Whitstable, taken from "All the Year Round", of November 26, 1859, is worth every inch of the space it occupies; it will be recognized as authentic by anyone who has worked in the creeks and estuaries of the east coast of Britain. There is an interesting anthology containing not only Sam Weller's "two very remarkable facts" concerning the oyster, but much less-familiar material from Pepys, John Evelyn, Robert Boyle and others.

Maurice Burton's scientific contributions fit easily into the scheme of the book, dwelling rather more

on the curious and bizarre features of the oyster's biology than is permissible in a scientific monograph. It is a pity that he repeats the clearly disproved suggestion that the dumping of trinitrotoluene and other explosives was responsible for the catastrophic losses among oysters in Britain in 1920.

Of Prof. Yonge's book it is only necessary to say that, while it upholds the high technical standard of the New Naturalist Special Volumes, it is more readable and of wider interest than some of the earlier books in this series. Clearly his main difficulty has been to compress adequate references to all the major studies on oysters into a monograph of 200 pages. It may be suggested that the description of the extremely scientific oyster culture of Holland should not have been limited to less than a page, but the extraordinary system used in the Norwegian polls has also (necessarily) to be described in a couple of paragraphs. However, all the important references are here for anyone with a desire for further knowledge. The author begins: "This is a small book on a very big subject", and, towards the end, he writes of the consciousness of lack of knowledge about commercially valuable oysters even though they have been more closely studied than any other marine animals. He may rest assured that his latest contribution will help us considerably to appreciate where effort should be applied.

H. A. COLE

LIVESTOCK IN AFRICA

The Indigenous Livestock of Eastern and Southern Africa

By I. L. Mason and J. P. Maule. (Technical Communication No. 14 of the Commonwealth Bureau of Animal Breeding and Genetics, Edinburgh.) Pp. xv+151+179 plates. (Farnham Royal, Bucks: Commonwealth Agricultural Bureaux, 1960.) 45s.

AS might be expected, the indigenous livestock of Africa, with few exceptions, have not been improved, even for work purposes, to the extent of those in Asia where ancient civilizations existed. As Norman Wright points out in his foreword, it will probably be easier to increase the production of native breeds adapted to their particular environmental conditions than to import improved breeds unsuited to the local hazards of environment and disease. However, perhaps one might add, except where by suitable crossing and selection the production of the one is combined with the adaptability of the other as in the case of Bonsmara cattle and Dorper sheep.

The book attempts to classify the different types of livestock by various morphological characters—cattle by the position and size of the hump and horns: sheep by their tails, thin, fat or fat rumped; and goats by the length of their ears. Where available, facts are given concerning their size, weight and milk production together with a large number of excellent photographs; references to original descriptions are quoted. For most types estimated numbers and their distribution in different countries are given, but one misses, except in a few cases, an account of the ecological conditions of temperature, altitude, rainfall and type of vegetation with which each type is associated. Nomenclature forms a problem throughout and in the absence of well-recognized

names the authors have adopted the tribal name. With camels, for example, the different tribes often use them for different purposes—pack, riding or milk as well as meat.

As might be expected, the distribution of the different species varies widely; the horse and ass are mainly confined to the north and south of the area, while cattle take their place in the intermediate zone. With cattle too, the zebu type with a large thoracic hump and short horns tends to follow the coastal areas, whereas the sanga type with its small, muscular cervico-thoracic hump and large horns tends to occupy inland areas. One interesting sidelight is that in many breeds individuals either polled or with loose hanging horns exist, showing the widespread incidence of this mutation. The genes for all-the-year-round breeding which occur in some types of sheep and goats might well be introduced into Britain. Indigenous breeds of pigs seem to be absent from Africa, for most of the types appear to conform to the breeds of the countries which first colonized the areas and even the small Bantu pig shows evidence of Asiatic origin.

The information given in this book should form a guide as to which of the various types it will be worth while to concentrate on for improvements in production, for Africa is a continent with a great potential for increased food supplies.

JOHN HAMMOND

PEOPLE AND PARROTS

Verbal Behaviour

By Prof. B. F. Skinner. Pp. x+478. (London: Methuen and Co., Ltd., 1959.) 42s. net.

AS a psychologist, Prof. Skinner has tackled the basic problem of verbal behaviour: he has not speculated about primeval grunts or the metaphysics of the word and the world, he has simply asked how the individual acquires his verbal skills. This makes such good sense that one wonders why one had not thought of it before: "We are specially reinforced by speakers and writers who say what we are *almost* ready to say ourselves—who take the words 'off the tip of our tongue' . . . The listener may refuse credit and exclaim *Why didn't I think of that?*, but he must have 'thought of it' to some extent if he accepted it immediately as an effective metaphor or a really apt remark" (p. 272).

The book does not attempt a quantitative or experimental analysis of verbal behaviour: "The emphasis is on an orderly arrangement of well-known facts, in accordance with a formulation of behaviour derived from an experimental analysis of a more rigorous sort" (p. 11). The concepts applied are those of 'operant conditioning', discussed by the same author in his book, "Science and Human Behaviour" (New York, 1954). Given a repertoire of loosely organized instinctual behaviour patterns or responses acquired in other situations, the animal extends its control of the environment by discriminating those of its activities which pay off. The baby gradually converts his babbling to words by progressively accurate discrimination and reproduction of the responses which his parents reward and which he can practise to himself since he both speaks and hears. "At this stage the child resembles a parrot, which is automatically reinforced whenever its vocal produc-

tions match something heard in the environment" (p. 164).

Prof. Skinner sets off from this position and gives us a conducted tour of verbal behaviour. This is fascinating: we catch glimpses of magical thinking, psychotherapy, symbols, metaphors, puns, non-Freudian slips, spoonerisms, 'Finnegan's Wake', speech disorders, generalization gradients, universals, linguistic philosophy, stylistic devices, and ways of making people say what we want without actually beating. These are, of course, only glimpses—the value of the book is that it penetrates the clouds in so many places, for example, p. 314, "It is because our behaviour is important to others that it eventually becomes important to us", and p. 7, "We have no more reason to say that a man 'uses the word *water*' in asking for a drink, than to say that he 'uses a reach' in taking the offered glass".

From his analysis the author derives several new concepts—the mand, the tact, the autoclitic—and this is a considerable contribution in addition to the stimulation and insight he gives on the way.

Although one would like to recommend this book to everyone interested in any aspect of language, this might not be fair. This is a psychologist's book, and there is not much exposition of the basic concepts of operant conditioning theory in it. For those who have no acquaintance with the field the book would be harder reading: it would nevertheless be rewarding, and the reader could always refresh himself with forward glances at the later parts from time to time.

P. R. F. CLARKE

THE HARVEY LECTURES

The Harvey Lectures

Series 53, 1957–1958. By Dr. John H. Dingle, Dr. Frank Fenner, Dr. H. Fraenkel-Conrat, Dr. Joshua Lederberg, Dr. Arthur Kornberg, Dr. Albert H. Coons, Dr. Daniel Mazia, Dr. J. Gough, Dr. John H. Gibbon, jun. (Delivered under the auspices of the Harvey Society of New York.) Pp. xiv+254. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959) 7.50 dollars.

THE Harvey Society has again amply fulfilled its constitutional aim of "the diffusion of scientific knowledge of the medical sciences". The lectures here published are too different to be adequately summarized, but their interest and variety shows the extent to which medical science now draws on general biology, and, in turn, fertilizes the latter. For example, Dr. F. Fenner's work on myxomatosis is of interest to the anthropologist and student of evolution as well as to the virologist. He points out that few of the viruses we know to-day could survive in scattered populations such as those of Palaeolithic man. How then have they arisen? The myxoma virus, from producing a benign tumour disease in the Brazilian rabbit *Sylvilagus*, has become in a short time a virulent general disease of the dense populations of *Oryctolagus*, which have spread from the Mediterranean and especially to Australia. Fenner shows how this spread has been made to provide information about the evolution of viruses, inevitably a difficult study since "viruses exist only to-day, what happened yesterday is already rumour".

Dr. H. Fraenkel-Conrat discusses the tobacco mosaic virus as a "treasure-trove of chemical surprises", especially about the aggregation of protein and nucleic acid *in vitro* to form active virus. He emphasizes the difficulties due to the lack of methods for investigating the fine structure of polynucleotides.

Dr. J. Lederberg provides a fascinating account of sexual processes in bacteria by the movement of a chromosome from one cell to another of a pair. Since this happens progressively the chromosome can be broken at varying stages and the linkage relations studied. "The power and scope of these methods was illustrated . . . by the fact that the simple operation of mixing two mutant cultures on a few selective agar plates can generate information on 10⁶ incidents of re-combination—an easy match for the reproductive potentiality of the entire human species".

Other lectures by Dr. D. Mazia on cell division, Dr. A. H. Coons on lymphoid tissue, Dr. A. Kornberg on deoxyribonucleic acid are no less interesting, and the whole volume, though not designed as a unity, provides a striking demonstration of the depth and breadth of medical science.

J. Z. YOUNG

REGENERATION IN ANIMALS

Asexual Propagation and Regeneration

By M. A. Vorontsova and L. D. Liosner. Translated from the Russian by P. M. Allen. Edited by F. Billett. Pp. xxiv+489. (London and New York: Pergamon Press, 1960.) 70s. net.

THE study of regeneration in animals has been pursued sporadically since antiquity, was caught and made scientific by Spallanzani, and received the blessing of philosophy from Voltaire. More to the point, its modern history offers us a perfect blend of the marvels of Nature with intellectual challenge, and adds more than a prospect of clinical relevance. Yet few books in English have been devoted to it, and of them only A. E. Needham's most useful, but brief, review is of service in introducing the present-day student to an enormous literature.

The appearance of Marie Vorontsova's book in translation is therefore an important event. It proves to be a happy one in some ways, a disappointing one in others. One cause of disappointment is likely to be all too apparent to the casual reader, and it may be well to mention it at once.

It is rightly felt that complaints about misprints and such-like minor errors argue for intellectual poverty in a reviewer. The price must sometimes be paid, and the making of this book cannot be allowed to pass without protest. The chief offence is in the re-transliteration of the names of Western authors. Dreisch, Abelo, Wolf, Gertwig, Navil', Bronsted and Shul'ts will present little difficulty to regeneration workers. But who is Dzhidzh? Luckily he worked with Rose and can for that reason be traced as Gidge. There are also some slips of substance in the text, most of which are so obvious as to be more irritating than dangerous.

Of the book itself one can speak with qualified pleasure. The authors begin with a brief survey of the modes of asexual reproduction in animals and their incidence. Spore formation and partheno-

genesis are quite reasonably excluded, but the absence of reference to polyembryony is odd. In the few insects and mammals which habitually resort to it, the process is biologically important and full of interest, but it has, of course, little kinship with adult regeneration and is presumably ignored on that account.

The second main section of the book is a treatment of physiological regeneration, that is, of processes of tissue replacement inseparable from normal life. Here the authors are content to discriminate between this and reparative regeneration (that is, replacement following traumatic loss) and to give examples demonstrating the ubiquity of tissue replacement in the animal kingdom.

The last section, constituting more than three-quarters of the whole, is devoted to reparative regeneration, a field in which both authors have themselves done distinguished work.

Here we are given an excellent introductory account of 'true' regeneration in all groups of animals in which it has been demonstrated. The emphasis is, of course, on experimental work designed to reveal the cellular genealogy of regenerates, the causal relations during regenerative morphogenesis, and the factors controlling the incidence of the capacity to regenerate. There are a few important omissions of which nerve regeneration is an example. In partial recompense the large Russian literature is properly represented without depriving non-Russian authors (of works published up to 1955) of their due attention. A final chapter discusses such generalizations as have been proposed to describe regenerative phenomena, or to relate them to asexual reproduction.

The authors are occasionally severe. This is a merit when one happens to agree with them, a blemish when one does not. The concept of regeneration 'fields', for example, is so treated that the reader senses a lack of normal human sympathy for an admittedly inadequate attempt to describe important and puzzling phenomena. They are sceptical about the role of neoblasts in planarian regeneration, and frankly hostile to the claims for a unique role for interstitial cells in hydrozoans. In these, and other matters, their attitude is not so much unreasonable as unduly dogmatic and tinged with a little self-righteousness. Nevertheless, on most of the difficult and long-standing problems of regeneration their views will command agreement or, at very least, respect from the majority of their colleagues. It is certainly of great value to have them so clearly stated.

D. R. NEWTH

NUTRITION AND DIETETICS

World Review of Nutrition and Dietetics

Edited by Prof. Geoffrey H. Bourne. Pp. viii+272+7 plates. (London: Pitman Medical Publishing Co., Ltd., 1959.) 60s. net.

THIS volume is the first in an annual series. In the preface the editor refers to the "avalanche" of papers which now envelops students of nutrition and makes it difficult for them to keep in touch with advances in the different branches of the subject. He claims that there is ample scope for a new publication which will provide "more lengthy and discursive reviews than those published in conventional

journals", adding that the reviews will provide critical evaluation and bear the imprint of their authors, whose views and theorizing will be welcomed.

The first number contains ten reviews of a wide variety of subjects, including the effects of androgens and oestrogens on the metabolism of proteins and the growth of tissues, the biosynthesis of vitamin C, basal metabolism in the Japanese population, nutritional factors in anemia, the use of isotopes in nutrition research, and the nutritional requirements of embryos. The reviews originate in five countries, and the authors are recognized authorities in the fields covered. The volume opens appropriately with a scholarly article on "The History of Nutrition" by E. V. McCollum—almost the last survivor of the founders of modern nutritional science—which contains a good deal of information not generally known. For example, McCollum states that J. B. A. Dumas, the French chemist, was "the first man to suggest that a diet which supplied only protein, fat and carbohydrate was inadequate for the support of life", a conclusion based on experience in the siege of Paris in 1871, when efforts to devise synthetic 'milk substitutes' for infants failed. McCollum records that when he himself was engaged in pioneer research on vitamins in the first decade of the century, he did not know of the fundamental discoveries of Eijkman and Grijns in Java on rice and beriberi, made during the years 1896–1901, because these "were all published in journals devoted to hygiene and medicine not usually read by chemists". It was not until 1913 that he learnt about them, through books written by Vedder and Funk. Apparently keeping abreast of the literature presented problems in those days also, though not the same problems that confront the modern scientific worker.

The other reviews are generally of high quality, clearly summarizing existing knowledge. They differ, however, in their value to the average nutrition research worker. "The Biosynthesis of Vitamin C", by C. J. King and R. R. Becker, deals with a very specialized field and the same may be said of "Neoplasia and Nutrition", by T. A. McCoy. The articles "Treatment and Prevention of Kwashiorkor" by a group of workers at the Institute of Nutrition for Central America and Panama, and "Nutritional Factors in Anemia", by G. R. Wadsworth, are of wider general interest. "Basal Metabolism in the Japanese Population", by Shinjiro Suzuki, brings out the fact that the body size of the Japanese has steadily increased since 1900, with an interruption associated with war and post-war food shortages; this review is agreeably but rather unnecessarily enlivened by a photograph of two attractive Japanese women divers. The last review in the volume, by A. Giroud, on the nutritional requirements of embryos, is unusual and informative; in spite of 350 references the author succeeds in giving a lucid account of a recently developed field of research likely to be of considerable practical significance.

It is difficult to assess the contribution which this "World Review" is likely to make to nutrition research and applied nutrition and to judge whether it will fulfil a real need. The editor has undertaken a formidable task and faces much competition in the shape of other review journals of longer standing. The first volume sets a high standard which may not be easy to maintain.

W. R. AYKROYD

PLASMA PROTEINS

The Plasma Proteins

Edited by Frank W. Putnam. Vol. 1: Isolation, Characterization and Function. Pp. xv + 420. Vol. 2: Biosynthesis, Metabolism, Alterations in Disease. Pp. xv + 518. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) Vol. 1, 12.50 dollars; Vol. 2, 14.50 dollars.

THE objective of this treatise was to provide an account of the physical and chemical properties of the plasma proteins, their function, biosynthesis, metabolism and alteration in disease. To attempt to produce an authoritative and up-to-date work on such a vast subject is a tremendous undertaking requiring the utmost co-operation between editor, authors and publishers.

We are told by the editor in his preface that the entire treatise was completed within eighteen months of the first invitation to the authors, and that Volume 1 was published within one year of the first deadline for manuscripts. This is probably true also for Volume 2 which followed only a few months afterwards. Those of us who have had to wait two years and often much longer for our articles to appear in print in collective volumes will be enviously impressed.

There is no doubt that this publication has succeeded admirably in its objective. It is impossible to do justice to it in a short review; but a glance at the chapter headings and the names of the authors, all of whom are experts in the fields they write about, will give some idea of the extent and authority of treatment. The first three chapters are on methodology, and deal with fractionation and isolation by precipitation techniques (R. B. Pennell), electrophoretic and ultracentrifugal methods (G. R. Cooper) and ion-exchange chromatography (E. A. Peterson and H. A. Sober). Molecular parameters of purified plasma proteins are then discussed by R. A. Phelps and F. W. Putnam. Then follow detailed discussions of individual and particular groups of plasma proteins (albumin, by J. F. Foster; γ -globulin and antibodies, by R. R. Porter; macroglobulins and antibodies, by H. G. Kunkel; glycoproteins, by R. J. Winzler; metal binding proteins, by C. B. Laurell; lipoproteins, by F. T. Lindgren and A. V. Nicholls; plasma enzymes, by W. H. Fishman, and circulating hormones, by H. N. Antoniades). R. G. MacFarlane contributes an article on the very complex blood coagulation system. Emphasis throughout the treatise is on human plasma proteins, but there is a chapter by R. L. Engle and K. R. Woods on comparative biochemistry and embryology, wherein data for many species are presented. Biosynthesis is covered by H. S. Anker. Alteration in disease occupies two chapters; M. L. Peterman describes altered patterns and F. W. Putnam surveys the properties and biosynthesis of abnormal globulins. Finally, genetic alterations in human plasma proteins are described by D. Gitlin and C. A. Janeway.

All this mass of material is brought together for the first time in English, and treated from the modern experimental point of view. Despite the large number of contributors there is no serious duplication and there are frequent cross references from one chapter to another. The subject-matter is presented in a logical way, and continuity is preserved.

Despite recent and rapid advances in some of the fields discussed, the comprehensive treatment, wealth

of tabular data and the many references give this treatise a lasting value. Not unimportant is the clarity of style; most of, if not all, the chapters can be read with pleasure as well as for instruction. All this is a tribute not only to the authors but above all to the editor.

This treatise will be of the greatest value to all who have anything to do with plasma proteins; it is undoubtedly a major contribution to the literature on proteins.

R. CONSDEN

The black-and-white figures in this volume leave something to be desired: the characteristic pattern of the leaves of *Coriaria* (Fig. 24) has been quite lost, and the upright shoot of *Halesia* (Fig. 45) gives no idea of the gracefully pendent flowers; *Taxus baccata* var. *adpressa* (Fig. 65) looks far more like a species of *Pernettya*. It is not, however, the minor defects of this series which one regrets: it is the faint atmosphere of stagnation. Current interest in wild and cultivated plants is more lively and inquiring than the authors seem to realize.

B. L. BURT

FERNS, MOSSES, SHRUBS AND TREES

British Ferns and Mosses

By Peter Taylor. (The Kew Series.) Pp. 231+15 plates. (London: Eyre and Spottiswoode (Publishers), Ltd., 1960.) 25s. net.

Garden Shrubs and Trees

By S. G. Harrison. (The Kew Series.) Pp. 318+15 plates. (London: Eyre and Spottiswoode (Publishers), Ltd., 1960.) 25s. net.

THESE new volumes in the Kew Series on British plant life are uniform in format and outlook with the two already published, and maintain the same rather humdrum level. At just one point the atmosphere changes. Mr. Taylor's account of the horsetails occupies some 32 pages, and one is immediately aware of his personal enthusiasm for this much neglected group. Backed up as it is by Miss Webster's admirably clear illustrations, this is surely the best account available and is one that every British botanist and field naturalist will wish to have at hand. The ferns themselves are displayed competently but unexcitingly. There is a resolute determination in this series not to frighten any reader by too much modern science. It is a misguided attitude. Sir Joseph Hooker knew better, and in the preface to his "Student's Flora" referred to "those physiological and morphological observations on British plants which have of late given so great an impulse and zest to botanical pursuits". He regretted that he could not fulfil his original intention of giving details of such work. The incorporation of the results of Prof. I. Manton's magnificent experimental studies on British ferns in a popular book of this kind is just what is needed to give a fillip to field botany.

Any selection of material invites criticism, and Mr. Harrison's choice in "Garden Trees and Shrubs" cannot escape it. How could he include *Erica carnea* and omit *Calluna*? Or mention six species of *Magnolia* and not one of the beautiful *M. sieboldii*-*M. wilsonii* group? Also, why no single yellow rose (such as *R. hugonis* or *R. xanthina*) to stand beside the red *R. moyesii*? These are strange omissions in the presence of *Decasmea fargesii* and *Griselinia littoralis*. The chosen plants are, however, neatly and lucidly described, and the book, with its pleasant coloured illustrations, will yield some informative browsing for botanically minded gardeners. It is not really a book for identification purposes, for the key will often work only for the actual species described, and a different one may come down to the wrong genus. *Ledum* (keyed out on p. 37) has free petals and should be placed next to *Skimmia* and *Cotonaster* on the previous page.

MICROSCOPIC STAINS

Encyclopaedia of Microscopic Stains

By Edward Gurr. Pp. xii+498. (London: Leonard Hill (Books), Ltd., 1960.) 95s. net.

THIS book is to be regarded as an F_1 hybrid (Conn $\times$ Colour Index). It retains the characteristics of both parents, being intermediate in size between the slimmer Conn and the stout Colour Index (first edition), and deriving its style and format largely from the former.

Most of the book (420 out of 498 pages on very thick paper) takes the form of an alphabetical list of dyes, together with synonyms, molecular weights, empirical and structural formulae, and solubility data. These last, giving solubilities in water, ethanol, 'Cellosolve', ethylene glycol and xylene, are particularly useful in practical histology.

Each dye is listed with a number and trade mark ('Mochrome') so that, although no price is mentioned, an aura of the catalogue overhangs the whole work. In his preface the author defends his own system of numbering on account of its stability by comparison with alternative systems (the second edition of the Colour Index differs widely from the old one). If the constancy of the dyes listed is as good as that of the numbering system there is much to be said in its favour.

The descriptive notes which accompany each listed dye give numerous references to possible and actual uses, but, in a disconcertingly large number of cases, the author has been unable to find any histological or histochemical use to justify the inclusion of the dye in his lists. In some cases dyes with identical formulae, molecular weight and solubilities are recorded as separate items, without the appropriate synonym (brilliant croceine; croceine scarlet).

The author makes a case for regarding the molecular weight of a dye as an important indicator of its properties. He therefore presents, at the end of the book, a table of molecular weights as an aid in "selecting dyes for particular purposes".

Two other sections, perhaps added as an afterthought, briefly concern the diazonium salts used in histochemistry and the tetrazolium salts similarly employed. In the case of the former the quoted molecular weight is relatively useless unless the concentration of vehicle and stabilizer in the commercial product is known.

Histological departments and students of histology may like to have this book on their shelves; it contains a large volume of interesting and necessary information.

SYNTHESIS OF APPLIED PALAEONTOLOGY

Paléontologie Stratigraphique

Par Prof. H. Termier et G. Termier. Pp. ix+515. (3,425 figures). (Paris: Masson et Cie., 1960.) 148 N.F.

Atlas de Paléogéographie

Par Prof. Henri Termier et Geneviève Termier. Pp. 100, avec 36 figures en couleurs et 8 figures. (London: Masson et Cie., 1960.) 16 N.F.

THERE is in geology a great need for the publication of comprehensive works which draw together and synthesize the vast quantities of observational detail which have been rapidly accumulating in the past decades all over the world. Similarly there is a need for the critical comparison and co-ordination of the innumerable ideas and speculations that have been published in original papers in a great many different fields. We ought to be truly grateful to those who are prepared to step out of the fray (where glory is won), survey the field and report on the state of the battle. The task they perform is seldom rewarding to themselves, while the works they write involve a great deal of labour. Unfortunately the need for such works and their rarity make us very critical, for so often when they are published we are disappointed to find they are not those for which we were waiting.

Thus we ought to be delighted with these two excellently produced volumes by the indefatigable team of Prof. and Mme. Termier. However, there is no doubt that in spite of the really excellent drawings of the "Paléontologie Stratigraphique" and the equally beautifully executed maps of the "Atlas de Paléogéographie" a feeling of disappointment is not to be avoided.

The "Paléontologie Stratigraphique" is neither palaeontology nor stratigraphy. It consists chiefly of a collection of figures of fossils arranged chronologically, and it attempts to survey the whole faunas and floras of each System, the larger Systems being broken down into Lower and Upper, or Lower, Middle and Upper. The matter is to some extent further organized by an introductory article on each System, or division of a System, dealing with the faunas or floras characterizing particular major facies developments. Tables of zones are provided at the end of each section. It is of course not possible to be truly comprehensive even in 515 pages and with 3,425 figures. The choice of genera for treatment is eclectic. Some are important zoologically, others as zone fossils, and many are merely abundant. In consequence neither the evolutionary nor the purely stratigraphical account is as complete as it could have been if it alone had been the object of the book. This is in fact a museum in a book, and for the student who has not access to a really good palaeontological collection it can be a really valuable reference book (though he will not be able to afford to buy it for himself). For an encyclopaedic work of this kind it is exceptionally accurate and up to date. A weakness, however, is the lack of any indication of the magnification of a large number of figures which differ greatly in size from the originals.

The "Atlas de Paléogéographie" consists of 36 maps—each a Mercator projection of the whole world—which originally appeared in the first volume

of the authors' "Traité de Géologie". These maps differentiate, at successive stratigraphical horizons, subsiding and non-subsiding seas (in two tones of blue) and show by means of photographs the distribution of vulcanicity, mountain ranges, coral reefs, forests and other geographical features as well as particular fossils. Arrows show the direction of migration of faunas and floras. Had the maps merely summarized the broad distribution of the regions of thick sedimentary accumulation in the past, and the known distribution at particular times of other sedimentary phenomena and of particularly significant fossils, they might have had some value. But the maps purport to do much more than this; and to the extent that the reader accepts them as established geographical reconstructions and interpretations of migration routes, so is he misled. Moreover, on account of the small scale of the maps compared with the size of the symbols, together with the fact that the maps do not represent true instants of time, an altogether false impression is presented of the extent of the available data. In the hands of an undergraduate, or of a layman, this can be a dangerous book. The experienced stratigrapher will prefer his own speculations.

S. SIMPSON

METALS IN SURGERY

Metals and Engineering In Bone and Joint Surgery

By Prof. Charles Orville Bechtol, Prof. Albert Barnett Ferguson and Prof. Patrick Gowans Laing. Pp. vii+186. (London: Baillière, Tindall and Cox, Ltd., 1959.) 64s.

SINCE the earliest times the surgeon has been in need of some inert material which he can introduce into the body to unite damaged tissues, or to replace structures that are beyond repair. Over the years, however, implantation of a wide variety of metals gave disappointing results, owing either to the mechanical failure of the implant or to its inflammatory effect on the surrounding tissues. Not until shortly before the Second World War was it realized that this lack of success was due to metallic corrosion, and even later before the part played by such factors as fatigue and fretting was really appreciated. It then became apparent that the orthopaedic surgeon had to be not only a master of his own art, but also conversant with the crafts of the physical chemist and the engineer.

It is this extra knowledge, in concise and palatable form, that the authors of this book set out to give him. Starting with a brief survey of the historical aspects of the subject, with adequate references, they pass on to consider the theory of metallic corrosion, at first in general terms, and then as applied to the various metals that have found application in surgery, indicating how such corrosion may be exacerbated by the incorrect choice or treatment of the metal to be implanted. Next they consider the structure and mechanical properties of bone, and show that a thorough understanding of such properties is necessary for the correct design and use of metallic implants. Finally, they discuss the healing process as applied to fractures, and describe in detail the various ways in which metals may be used for the internal fixation of broken bones.

Any attempt to correlate three such different disciplines as surgery, electrochemistry and engineering must of necessity result in a treatment which to a specialist in any of these subjects may appear as superficial. It might possibly be argued that a book of this kind would have been of more value had it been written with the collaboration of a chemist and an engineer. Such collaboration, however, might well have resulted in a treatment too long and detailed to be of practical use to the surgeon for whom, after all, the volume is intended.

The book is well illustrated, with many references to the original literature; and while the reviewer might point to a few minor blemishes such as the misspelling of his own name, such slips in no way detract from a work that should be of real value to those for whom it is written. E. G. C. CLARKE

RHEOLOGY

Rheology

Theory and Applications, Vol. 3. Edited by Frederick R. Eirich. Pp. xvi+680. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 21 dollars.

"EIRICH" is already a classic in rheological literature, even if it cannot be said to have brought about "a better understanding of the essential unity of rheology"; a hope expressed in the preface to Vol. 1.

The present volume contains little that will unify; rather it consists, like its predecessors, of a number of disconnected essays, differing somewhat widely in merit, on applications of rheology to various systems. It has still not been possible to establish an agreed set of symbols, even for the most widely used terms; but, unlike some of the chapters in previous volumes, each of these essays includes an adequate table of the author's choice of symbols.

Vol. 3 contains less material already published in book form by the same authors than did its predecessors; but there are still many pages of repetition of well-known classical treatments already available in other text-books. This reflects vestiges of the earlier idea, which can scarcely be maintained, that this excellent series of books would prove not only necessary but also sufficient for many rheologists.

Following these general criticisms, it is right to say that many of the essays are really admirable. Especially praiseworthy are the first three chapters: B. H. Zimm's essay on polymer chain models for dilute solutions; S. Oka on principles of rheometry; and B. E. Conway and A. Dobry-Duclaux's description of electroviscous effects.

Chapters 4-10 are concerned with the applications of rheology to different materials: latex, printing ink, pastes and paints, sand- and clay-water mixtures, inorganic glasses, concrete, and cross-linked polymers.

The "Atomistic Approach to the Rheology of Sand-Water and Clay-Water Mixtures", by W. A. Weyl and W. C. Ormsby, reflects the almost compulsive urge of some rheologists to insist on an 'atomic', as distinct from a phenomenological, explanation of all experimental data. Rheology, like all other branches of science, is concerned with generalizing, co-ordinating and relating diverse phenomena.

In many cases an 'explanation' in terms of molecular structure is both possible and desirable. Other phenomena, such as those dependent on the conditions of packing of large aggregates, do not readily lend themselves to an 'atomic' approach. The authors of this chapter seem almost ashamed that everything cannot be explained in atomic terms.

Chapter 11, by D. W. Criddle, is concerned with interface rheology, and the remaining five chapters deal with industrial processes in relation to lubrication, adhesion, moulding, spinning and screw extruding.

The volume is very expensive, but the production is excellent, and there appear to be few misprints. It is good to learn that it is likely that this will not be the last volume of "Eirich". So far, scarcely any mention has been made of biological systems. A volume, or at least a part of a volume, devoted to biorheology would now be useful, since it would seem to be about eight years since any text-book has appeared on this subject, and much work has been done meanwhile. G. W. SCOTT BLAIR

CONSTANTS OF BINARY SYSTEMS

The Physico-Chemical Constants of Binary Systems In Concentrated Solutions

By Prof. Jean Timmermans. Vol. 3: Systems with Metallic Compounds. Pp. xiii+1322. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 270s.

THE preparation of this volume was supported by a grant from the Union Minière du Haut-Katanga, which is especially interested in this kind of binary system. Although more than half this book is devoted to tables of the properties of binary systems of which water is one component, no solubility data as such are listed. Presumably the author did not wish to include information already collected elsewhere (for example, in Seidell's tables): but nevertheless solubilities do appear in a disguised form as freezing curves. However, the information on freezing curves is not as useful as it might be because the solid phase in equilibrium with the solution is not often indicated. These omissions are particularly unfortunate since freezing curves represent a large proportion of the data.

The notice to users claims that the same properties are tabulated as in the earlier volumes (see *Nature*, 186, 918; 1960); but in fact scattered information is included on other properties such as activities, lattice constants, Verdet's constant, X-ray absorption, osmotic coefficients and the compositions of isopiestic solutions. For some systems values of these quantities are given, but for others only the name of the author and a date are listed.

The compilation is not a critical one and there are considerable discrepancies among the tabulated values. The author in the preface ascribes these errors to inadequacies in the measuring apparatus as well as to the use of impure specimens. Considering the early date of many of the values included it is not surprising that there is some lack of agreement.

This volume is even more expensive than Volumes 1 and 2, and like them, it will probably not be purchased by many private individuals. Every science

library should possess a copy, however, because when Volume 4 (containing the bibliography and index) is available, the use of this book will save much time in searching the literature.

E. F. G. HERINGTON

FROZEN FREE RADICALS

Frozen Free Radicals

By Dr. G. J. Minkoff. Pp. ix+148. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 5 dollars; 36s.

FREE radicals are highly reactive species, but many radicals can be successfully immobilized in solid matrixes at low temperatures. In the past ten years the development of new techniques has led to a great acceleration of the study of the formation and trapping of radicals. This has been encouraged by the initiation in 1956 of a three-year programme of fundamental research at the National Bureau of Standards, where it was hoped that it would prove possible to utilize the stored energy of a high concentration of free radicals in the production of an efficient rocket fuel. Dr. Minkoff spent a year as a guest scientist at the National Bureau of Standards in connexion with this programme.

Drs. Bass and Broida of the National Bureau of Standards have recently edited a volume of sixteen contributions on the history and modern development of radical trapping, which is at present the most exhaustive review of the subject. In contrast, Dr. Minkoff's monograph can be particularly recommended as a well-co-ordinated introductory survey.

The first four chapters of the book are devoted to the history of radical trapping and a description of the modern techniques. Many of the early studies of the phenomena of light emission from the condensation products of discharges and of the reactions taking place in cold traps have been repeated. The stabilization of free radicals has been increased by the use of liquid helium as refrigerant, and descriptions are given of several Dewar vessels constructed for optical studies at liquid-helium temperature. Several methods for the detection of free radicals are given, with indication of their suitability for use when the radicals are trapped. Electron spin resonance has proved particularly valuable in this respect. Statistical predictions have been made of the maximum concentration of free radicals that may be trapped in various assumed models. However, all but one of these give limits which are much in excess of the experimentally determined maximum of a few tenths of 1 per cent as they do not allow for the nature of the matrix or the energy of recombination of the radicals.

The last three chapters of the book summarize the most important experiments published up to early 1959. Many pages are devoted to the observations on nitrogen atoms, as the repetition and extension of the early work gave much stimulus to the National Bureau of Standards programme. Atoms and small radicals have usually been produced in the gas phase and condensed at liquid-helium temperature. However, larger organic radicals are better stabilized by the irradiation of suitable solid solutions with ultra-violet or ionizing radiation. Liquid nitrogen is usually sufficed as refrigerant in these experiments,

in which the radicals may be the primary products of the irradiation or the results of reactions by the primary products. Free radicals have been found to be trapped in polymers, and are also believed to be important in biological systems. Reduced temperature is not necessary in these cases, and they are only briefly mentioned.

R. N. DIXON

NATURAL HIGH-POLYMER CARBOHYDRATES

The Chemistry of Plant Gums and Mucilages and some related Polysaccharides

By Prof. F. Smith and Prof. R. Montgomery. (American Chemical Society Monograph Series, No. 141.) Pp. x+627. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1959.) 144s. net.

PLANT gums and mucilages are complex carbohydrates and rank among the oldest articles of commerce. They are abundant and their applications are diverse, so that their use and importance are growing. The fairly recent unravelling of major parts of their complex structures provides a fascinating story, so that the appearance of this monograph is opportune.

The senior author, F. Smith, is one of the world's leading experts in the field, and the junior author is a well-known carbohydrate chemist—both of Haworth's Birmingham School—so that much was expected from them. Their labour and care are rewarded, for the book fully justifies the claim of the publishers that it contains everything that is known of these substances.

The first few chapters deal in a human and interesting manner with the function and origin of gums, their classification, isolation, detection and identification. A wealth of detail is provided, some of which, however, except for its historical importance, could perhaps have been omitted. Methods for the separation of polysaccharides generally are concisely described, and their analytical procedures are covered in a very long and exhaustive chapter. The rest of the book is devoted to the detail of the determination of the structure of the many gums, mucilages, exudates, etc., so far examined. The importance of periodic oxidation techniques and of methylation procedures, largely pioneered by the senior author, is brilliantly emphasized, and seeing the picture as a whole one is amazed at the wealth of knowledge we now have of these complex high-polymer carbohydrates.

Of particular value in connexion with structural work in the field is the provision of an appendix giving some of the physical characteristics of all the O-methyl derivatives of monosaccharides.

An important innovation is the account of studies of gum structure by means of specific immunological reactions which provide diagnostic micro-methods of growing importance.

The book is full of beautifully drawn formulae which make it of special value to the non-expert. It contains a most valuable series of references, and it is excellently printed and free from errors.

It will form a valuable addition to the library of every chemist, biochemist and plant physiologist, and can be highly recommended.

M. STACEY

ENZYMES AND METABOLISM

Advances in Enzymology and Related Subjects of Biochemistry

Vol. 21. Edited by F. F. Nord. Pp. v+521. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 12.50 dollars.

THIS volume of "Advances in Enzymology" contains a very important set of articles on some important lines of metabolism which have only recently been elucidated. The synthesis of purines and pyrimidines is covered by three reviews which supplement each other: "Enzymic Reactions in the Synthesis of Purines", by Drs. Buchanan and Hartman; "The Enzymic Synthesis of Pyrimidines", by Dr. Reichard; and "Folic Acid Coenzymes and One-Carbon Metabolism", by Drs. Huennekens and Osborn. In the past ten years the main lines of synthesis have been cleared up, with an appreciable increase in the number of known enzymes; some new and interesting enzymatic mechanisms are involved, and these are discussed critically in the first-mentioned article.

Other metabolic topics dealt with in the volume are oxidation and phosphorylation (in two reviews, by Dr. W. C. Schneider and Dr. D. E. Green, respectively) and the biosynthesis of carotenoid pigments (by Dr. T. W. Goodwin). Schneider's article reviews work on mitochondrial metabolism up to about 1957. Green's article is primarily concerned with the work of his own school on electron transport, which is discussed in terms of the special terminology which they have developed to express their view of the structural organization of enzymes in mitochondria. The enzymology of carotenoid metabolism is not as yet far developed, and Goodwin's contribution is necessarily mainly concerned with the chemistry of these plant products.

Two articles are concerned with the role of metals in enzymatic systems. Drs. Malmström and Rosenberg discuss (in English) the mechanism of metal ion activation of enzymes; Prof. Bamann and Dr. Trapmann are concerned (in the only article in German in this volume) with reactions in which metal ion catalysis may be regarded as a model of the enzymatic catalysis. They give an excellent picture of the field, but leave the impression that much remains to be done.

This volume will clearly remain for some time to come a standard reference for the topics discussed therein.

EDWIN C. WEBB

CONDUCTION IN SOLIDS

Electrons and Phonons

The Theory of Transport Phenomena in Solids. By Dr. J. M. Ziman. (The International Series of Monographs on Physics.) Pp. xiv+554. (Oxford: Clarendon Press; London: Oxford University Press, 1960.) 84s. net.

LITTLE more than four years elapsed after the discovery of wave mechanics before the basic principles of electrical and thermal conduction in metals were established, and such was the speed of the advance that within another four years, up to the end of 1934, the properties of individual metals, and even alloys, were being successfully analysed in terms of the new theory. The War brought progress

in this field almost to a standstill, but at its end a new generation of physicists with new techniques and new ideas took up the pursuit once more, and the past fifteen years have seen a vast accumulation of detailed information on the properties of solids of many kinds. Although during this time there has been little change in the underlying principles or even in the mathematical methods employed in the electron theory of solids, yet so great a refinement of treatment has been introduced and so many more experimental effects discovered that, as the author of the book under review states in his preface, it is now probably beyond the capacity of any one man to write alone a satisfactory account of the whole theory.

In his book Dr. Ziman has confined himself to an account of the transport properties of metals, semiconductors and insulators; a subject of which he is undoubtedly a master. The title of the book at once indicates the quantal aspects of the conduction processes. By analogy with the quantized electromagnetic field it has become fashionable in recent years to refer to quantized elastic waves in crystals as phonons, and the whole mechanism of conduction is visualized as the mutual interaction between the phonons themselves and between phonons and electrons. This is an attractive picture, but it can all too easily suggest an over-simplification to the incautious reader: unlike a photon, the nature of a phonon in an elastically anisotropic crystal depends on the direction of its motion. The scattering of an elastic wave in a crystal is a more complicated process than that suggested by the deflexion of a single entity described as a phonon.

In an interesting analogy the author likens the writing of a scientific text-book to the process of purification by recrystallization. The imperfections of original papers are filtered away and the precipitate forms as a crystal in which each atom seems inevitably to be in its right place. This is a flattering description, and many of those with experience of either reading or writing text-books would hesitate to compare them with the perfect crystal. Dr. Ziman's is an excellent book but it will no doubt share the common lot and in the fulness of time will require extensive modification and revision. To the present generation of students—of all classes—the book will surely prove invaluable. It develops a theory in a clear and logical manner; dealing first with the properties of phonons, then with the properties of electrons in a periodic field, and eventually with the interactions between these systems. In this way is unfolded the theory of thermal conduction in insulators, the theory of thermal and electrical conduction in metals, the effect of an external magnetic field on the resistivity, the de Haas-van Alphen and the anomalous skin effects, and much besides.

The mathematics of the book is kept within reasonable bounds although always sufficiently detailed to enable the diligent reader to follow the argument completely. Physical concepts are emphasized, and the book abounds with discussions of significant experiments. The style is graceful, and erudite quotations at chapter headings are provided for the diversion of the reader. The publishers, for their part, have done a good job: the type is clear and the diagrams beautifully reproduced. Altogether this is an excellent book and deserves to be widely read.

H. JONES

GAS DISCHARGES REJUVENATED

Plasma Physics

By J. G. Linhart. (Series in Physics.) Pp. xi+278. (Amsterdam: North-Holland Publishing Company; New York: Interscience Publishers, Inc., 1960.) 50s.

Basic Data of Plasma Physics

By Prof. Sanborn C. Brown. (Technology Press Books in Science and Engineering.) Pp. viii+336. (Cambridge, Mass.: The Technology Press of the Massachusetts Institute of Technology; New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1959.) 52s. net.

THERE cannot be many examples in the history of physics of an almost moribund branch reviving and blossoming with such vigour as happened in the past ten years to what used to be called 'conduction of electricity through gases' or 'electric gas discharges'. The resurrected science is called 'plasma physics', adopting the name which Irving Langmuir gave almost forty years ago to the tough 'substance' of gas discharges, the highly ionized, highly conducting gas. The revival was due in the first place to the hope of controlled fusion, and led in a few years to giant devices such as *Zeta*, *Stellarator* and *Ogra* which dwarfed not only the modest discharge tubes in which J. J. Thomson and Langmuir made their classical discoveries, but also the largest rectifiers ever made for power stations. It is now common knowledge how successful the plasma was in repelling these first attempts for heating it up to millions of degrees, how it managed to dissipate the energy by processes nobody had thought of. This led to a general sobering and a determination to study the plasma before trying to force it to do what it so evidently dislikes doing. There may be some legitimate doubt whether it will be ever possible to 'study the plasma' except by feeding energy into it in special configurations of electromagnetic fields, and whether such knowledge will ever add up to a general mastery; but the intention is certainly laudable.

It can be said with confidence that at the present there exists no better introduction to this complex subject than Dr. Linhart's book. The author has the three rare qualifications of experience, mathematical facility and inventive imagination. He also possesses didactic ability, but this will be appreciated only by those readers who share with him the advantages of mathematical ability and of an active mind. It is not a book which can be imbibed passively, or uncritically.

The first three chapters on motion of electrons and ions, fluid description of plasmas and equilibrium configurations are more or less conventional and will make fairly easy reading for postgraduate physicists. The author comes into his own in the far more difficult chapters on waves and instabilities, shock waves and relaxation processes. Unfortunately, the derivation of the Fokker-Planck equation is almost incomprehensible, which is particularly regrettable in a subject in which Einstein and Debye have created masterpieces of simple exposition. This, however, is a rare exception in Linhart's book. The final chapters on research on controlled fusion and other applications, though perhaps somewhat too brief, make excellent reading.

Prof. Sanborn Brown's book on "Basic Data of Plasma Physics" is not only an excellent text-book

on the more orthodox chapters of gas discharges, but also a reference book which one cannot afford not to have on the shelf. Many of the most valuable data in his book (on high-frequency breakdown, on diffusion and recombination) are the results of the researches of its author and of his collaborator, Manfred Biondi. While much of the material on elementary processes is covered also by Massey and Burhop's "Impact Phenomena", about one-half of the book which deals with breakdown conditions and with discharges is a happy complement to that other excellent work. The arrangement is so clear, with full description of the experimental methods and with all the relevant theory required to explain the data, that the book can be equally recommended to the student and to the expert research worker. D. GABOR

HYPERSONIC FLOW PHENOMENA

Hypersonic Flow Theory

By Wallace D. Hayes and Ronald F. Probstein. (Applied Mathematics and Mechanics, Vol. 5. Series of Monographs prepared under the auspices of the Applied Physics Laboratory, The Johns Hopkins University.) Pp. xiv+464. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1959.) 11.50 dollars.

THIS book will prove invaluable to the increasing number of students and research workers who are becoming interested in hypersonic flow phenomena. Although it is mainly theoretical, it is not such that it requires the reader to have very advanced mathematical knowledge. It should appeal to the engineer who has to tackle the practical problem of hypersonic flight just as much as to the physicist who wishes to acquire a physical understanding of hypersonic flow phenomena. Both authors have over the years made important contributions to hypersonic flow theory and are by experience fully qualified to write authoritatively on this subject, and thus to convey some of the knowledge they have gained in this important field of research, to interested readers of their book. Much of the material presented has not been published elsewhere and reference is also made to many Russian papers on hypersonic flow problems. Some of these are discussed in detail in the text.

The scope of the book is fairly wide, but it does not include any material on high-temperature gas dynamics and magnetogasdynamics. Throughout the text emphasis is laid on fundamental aspects of hypersonic flow and on the development of a soundly based theory. Semi-empirical theories are generally avoided except those which contribute in some way to the understanding of hypersonic flow phenomena. Theories which are based on wrong assumptions are not discussed though they may give good agreement with experiment.

In more detail, Chapter 1 is devoted to the consideration of the general features of hypersonic flow and some of the basic concepts used in the development of the theory. Chapter 2 is concerned with what is referred to as the 'small disturbance theory', as distinct from linearized theory, in relation to flow past slender bodies and gives similarity rules for determining the flow. Special reference is made to van Dyke, who first used the expression 'small disturbance theory' in his studies of flows in which the disturbances in velocity and pressure are small

compared with the velocity of the free stream and its dynamic pressure, but are not small compared to the velocity of sound and static pressure respectively, as is generally assumed in the conventional linearized theory. This chapter ends with a brief section on unsteady hypersonic flow and deals particularly with what is now generally known as 'piston theory'.

Chapter 3 is devoted to Newtonian theory and various modifications of it by Busemann, Lees and other writers. The theory is applied to two-dimensional and axi-symmetrical bodies and to the determination of optimum shapes. Shock layer structure and cross-flow phenomena are discussed, and a theory for unsteady Newtonian flow is developed. As first approximations to more general solutions based on the assumption that the shock layer is moderately thin, constant-density solutions are obtained in Chapter 4 which give information beyond that obtained from Newtonian theory. Cases considered include the wedge, the cone, the circular cylinder and Lighthill's solution for the sphere.

Chapters 5, 6 and 7 consider respectively the theory of thin shock-layers, blunt-body flows and shock-expansion theory, while Chapters 8 and 9 discuss hypersonic viscous effects. Chapter 10 deals briefly with free molecule and rarefied gas flows.

I would strongly recommend this book to students and research workers who wish to study hypersonic flow phenomena.

W. P. JONES

GEOCHEMISTRY

Methods in Geochemistry

Edited by A. A. Smales and Prof. L. R. Wager. Pp. vii+464. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 13.50 dollars; 94s.

IN V. M. Goldschmidt's definition of geochemistry (1933) are implicit quantitative composition of the Earth and its parts, discovery of laws controlling distribution of elements, and comprehensive analytical data on rocks, meteorites, waters, atmosphere, to include geophysical evidence on the nature of the Earth's interior. This considerably extends the more restricted scope as originally enunciated by F. W. Clarke in his classical "Data of Geochemistry" (1908), where the solid crust of the Earth is the chief object of study. B. Mason, in his "Principles of Geochemistry" (1952), brings evolution of the subject to more recent times, when he defines the tasks of the geochemist as "the determination of the relative and absolute abundances of the elements and of the atomic species (isotopes) in the Earth" and "the study of the distribution and migration of the individual elements in the various parts of the Earth (the atmosphere, hydrosphere, crust, etc.), and in minerals and rocks, with the object of discovering principles governing this distribution and migration". Thus over the years both theoretical and analytical phases of geochemistry have expanded enormously, so, likewise, have the various methods of attack on the problems involved. In the present volume the authors, with collaboration of a team of specialists, describe modern techniques at the disposal of the geochemist which go far beyond traditional chemical and geological approaches to secure desired analytical data. "It is a long way from the geologist's hammer

to the mass spectrometer and the nuclear reactor which are now sometimes the tools the analyst uses", as the authors naively remark in their introduction; what follows in this book gives all concerned a clear indication of how that gap is bridged to-day.

Modern geochemical methods include collection and preparation of material for analysis, here contributed by L. R. Wager and G. M. Brown. E. A. Vincent discusses gravimetric and volumetric analysis, flame photometry, colorimetry and related techniques. Spectrochemical analysis is dealt with by S. R. Taylor and L. H. Ahrens; fluorescent X-ray spectrography by H. I. Shalcosky; stable isotope geochemistry and mass spectrographic analysis by K. I. Mayne; mass spectrometric isotope dilution analysis by R. K. Webster; radiochemical methods by S. Moorbath; radioactivation analysis by D. Mapper; polarography by S. Moorbath and modern chemical separation methods by F. W. Cornish.

Of the above techniques, two comparatively recent procedures of remarkably high sensitivity have been added to the geochemist's weapons of attack available in geochemical analysis. One is the mass spectrometer isotope dilution method, which owes much to development of thermal ionization source mass spectrometers, also to present availability of separated isotopes of many elements; the other method is that of radioactivation analysis. Both procedures are adequately described in this book.

"Methods in Geochemistry" is a new departure in this science in that it is not only an up-to-date exposition of what the authors term "an almost embarrassingly wide choice of techniques for any given problem", but also because it brings together in one volume so much current information on geochemical research which chemist, geologist or physicist alike would have to seek in an otherwise voluminous international literature. The book is highly commendable, both in presentation and purpose.

H. B. MILNER

MOISTURE IN TEXTILES

Moisture in Textiles

By Dr. J. W. S. Hearle and Prof. R. H. Peters. Pp. ix+203. (Manchester: The Textile Institute; London: Butterworths Scientific Publications; New York: Textile Book Publishers, Inc., 1960.) 40s.; 6.50 dollars.

THE adsorption of moisture by fibres is such an unobtrusive phenomenon that it is, perhaps, not generally thought of as being a reaction in the usual sense of the word. The interaction of the two is, however, of very great practical significance, not only because of associated changes in weight, which are economically important, but also because of dimensional changes in yarns and fabrics consequent on fibre swelling. The mechanism of moisture adsorption is complex and the many theories which have been evolved are admirably surveyed in this book, which is based on a series of lectures given at the Manchester College of Science and Technology.

The book is arranged in thirteen chapters, written by seven contributors. Chapter 1 (P. S. H. Henry) deals with water in the atmosphere and the relevant definitions; seasonal and diurnal variations; and the insulating effect of buildings. This is followed by

a brief chapter (J. W. S. Hearle) on the structure of fibres. The measurement and interpretation of sorption isotherms are discussed in Chapter 3 (A. R. Urquhart), the emphasis being on cotton. Factors which affect sorption, particularly mercerization, are included. Chapter 4 (W. H. Rees) concerns heat of absorption, and thermal quantities are defined and interpreted, together with methods of evaluation; again, the effects of physical and chemical modification such as orientation, mercerization and acetylation are discussed. Chapters 5 and 6 (G. King) survey respectively two- and three-phase adsorption theories, and theories of multilayer adsorption. Rate of change of moisture content, the simultaneous diffusion of heat and moisture, and diffusion of moisture and solvents in fibre-forming substances such as sheet films and polymers are discussed in Chapters 7, 8 and 9 (J. Crank). These phenomena are of considerable practical importance in the bulk storage of textiles, and the theoretical treatment is directed to clarifying the basic mechanisms and to showing how the times of moisture transfer into or from any given package can be estimated from measurements on a standard package. In Chapter 10 (J. W. S. Hearle) the electrical properties of fibres are discussed, including the relation between dielectric constant and regain; the generation and dissipation of static electricity; and the electrical measurement of moisture content. Particular attention is paid to ionic theories of conductance. Chapters 11 and 12 (R. Meredith) are concerned respectively with the effects of moisture on the density and optical properties of fibres, and on the mechanical properties such as tensile and torsional strengths, creep; relaxation, and shear strengths. In the final chapter (J. S. W. Hearle) the retention by fibres of liquid water and the theoretical and practical aspects of removing water from fibrous masses by centrifugal and suction methods are surveyed.

The subject-matter is well presented and is accompanied by an excellent bibliography. J. W. BELL

FRENCH WITHOUT TEARS

An Introduction to Machine Translation

By Emile Delavenay. Pp. ix+144. (London: Thames and Hudson, Ltd., 1960.) 25s. net.

SEVERAL books on the mechanical translation of language have now appeared, generated in England, the United States, and the U.S.S.R. Hitherto, however, work in this field on the Continent has been singularly lacking, and, although in the past two years groups have started in the field, in France and in Italy, M. Delavenay's book is the first popular exposition of the French point of view which has been translated into English.

To say that the book follows well-trodden lines would be to do it less than justice, because any expository book must tend to do this. What is perhaps more important is that M. Delavenay's racy style has survived translation (by himself and his wife) and enlivens the reading of what can otherwise be somewhat dull matter.

The book starts with a few general remarks about the nature of translation and, in particular, about the impact of information theory on this art. Here, unfortunately, M. Delavenay allows his enthus-

iasm to get the better of him in suggesting that information theory is of great importance to machine translation. The fact is that information theory considers the statistical aspects of communication, but nowhere, so far as I know, does it make any reference to meaning, and meaning is the essence of translation.

After this somewhat philosophical start the book runs smoothly through aspects of computing machines and their relevance to the translation of language. It states clearly how a computer works, explains the coding into numerical form which is necessary to transform words into arithmetical quantities for processing in a computer, and then it goes on to discuss various aspects of computer processing of language.

After these preliminaries there is a historical approach. M. Delavenay, quite rightly of course, mentions the original Russian patent of Trojanski dated 1933, although he, like all other Western experts in this field, appears to have seen only the title page. He then goes on to trace the history up to 1955, and to indicate the way in which this subject has grown from an unimportant sideline in certain university laboratories to a large-scale activity in which some thousands of scientists are involved.

After this history there is an account of languages and of meta-language, and also an indication of how linguistic analysis can be performed on a machine. Much of this work follows the lines laid down by the Russian school of machine translators. M. Delavenay in this account makes a number of succinct comments on the virtues of the Russian approach to machine translation and seems much impressed by the Russian development of what is effectively a meta-language.

The next subjects to receive attention are syntax and morphology, and here in discussing the question of reducing storage requirements by the use of micro-glossaries, M. Delavenay gives an interesting example of a partial German translation in which only the most frequent words were translated, with the result that no meaning at all comes through, or alternatively in which only the technical words are translated, in which case the meaning is completely clear without any very good notion of what connecting words are present. This is, in a sense, a validation of the early work of Richens and myself, who proposed to ignore sentence structure and grammar completely and to concentrate on evaluating the technical meanings.

Having dealt with syntax, the last aspect of machine translation to be covered is that of lexical problems. Here there is a detailed consideration of different possible storage media, an indication of the way in which code compression can help in saving storage, an account of the processing of idioms, indications of means by which multi-meaning can be resolved and an analysis of the virtues and otherwise of the Thesaurus method. All these topics are of particular interest to specialists in the field, and it is useful to have the opinions of an expert who is not committed to any particular party-line on the relative merits of the different methods.

The book concludes with a look into the future, as M. Delavenay sees it, and finally, and most usefully, a long example of a machine translation from French into English.

There are a number of small errors which will irritate knowledgeable readers of this book. Many of the numerical data which are given are incorrect

for one reason or another. This does not appear to be due to ignorance on the part of the author because reference to the original French edition shows that the correct figures appear there. It is surely proof, if any is needed, of the virtues of a translating machine for technical material. Such a machine would certainly not have produced the lively text that M. Delavenay and his wife have done, but it would have ensured the factual accuracy of the figures which he gives. These blemishes are, however, quite minor, and the book can be unreservedly recommended as an introduction to this important art.

A. D. BOOTH

MATHEMATICS, GAMES AND ECONOMICS

Mathematical Methods and Theory in Games, Programming, and Economics

By Samuel Karlin. Vol. 1: Matrix Games, Programming, and Mathematical Economics. Pp. x+433. Vol. 2: The Theory of Infinite Games. Pp. xi+386. (Addison-Wesley Series in Statistics.) (London: Pergamon Press; Reading, Mass.: Addison-Wesley Publishing Company, 1959.) 75s. net. each volume.

THIS work is, in a broad sense, a contribution to the mathematics of decision making. Most of the material included is of recent origin, and the author himself has contributed substantially to the subject. It is concerned mainly with two-person zero-sum games. The subject-matter results largely from the research efforts of teams organized, or supported, by Stanford University, the California Institute of Technology, the Rand Corporation and the Office of Naval Research. As a result, mathematicians interested in this field, mathematical economists, and operational research workers will find the work almost indispensable, at least as a reference book, if they wish to be up to date.

Part 1 of the two-volume work is concerned with the theory of matrix games. Games are defined, the min-max theorem is presented, and the nature of optimal strategies for matrix games is considered. Various discrete games are solved, and these include an example from advertising where two political parties are engaged in an election campaign. Part 2, which completes Volume 1, is a comprehensive account of programming, both linear and non-linear. Computational methods are discussed, but not practical details, such as some of the problems which arise when an electronic computer is used; attention is given rather to the theory of the computational method. In the chapter on linear programming there are sections, as one would expect, on transportation and assignment, and on the warehouse problem and the caterer's problem. There are two chapters on mathematical methods applicable to economic models. One is concerned with theories of production, consumption and equilibrium, the other with welfare economics, models of balanced growth, and the stability of the equilibrium of price vector systems.

The second volume is concerned with infinite games, and after an introductory chapter on the nature and structure of such games, considers games with convex kernels. Then there are two chapters on "Games of Timing", a name coined in 1950 for games of tactical

duels. The study of the latter commenced in 1948 when the Rand Corporation "collected a team of mathematicians, statisticians, economists and social scientists to analyse the meaning and structure of 'the uncertainties of war' and to construct a blueprint for the optimal future operation of the economies of attack and defence in war". By now a great number of games of timing have been analysed, and something of a general theory has emerged. The volume concludes with chapters on infinite classical games and on poker and general parlour games. There is a very interesting analysis of the Le Her game, and it is evident that in various cases solutions are only now appearing of games of some antiquity.

Some general remarks may not be out of place. The work will be essential for anyone carrying out research in game theory or mathematical economics. But it will also be useful for students, especially new graduates entering this field. There is a comprehensive bibliography of more than 250 references and there are problems set at the end of each chapter together with solutions worked out in detail. One unusual feature is that Volume 2 repeats Chapter 1 of Volume 1, and also all the appendixes. These amount to more than one-fifth of Volume 2 and must increase appreciably the price of the volume. The reviewer can find little justification for this repetition, even though it is stated as having been done so that the volume may be read independently of Volume 1.

L. S. GODDARD

WATER SUPPLIES FOR SMALL COMMUNITIES

Water Supply for Rural Areas and Small Communities

By Edmund G. Wagner and J. N. Lanoix. (Monograph Series, No. 42.) Pp. 337. (Geneva: World Health Organization; London: H.M. Stationery Office, 1959.) 20 Swiss francs; 35s.; 6.75 dollars.

THOSE of us who live in highly organized communities in the humid regions tend to take water so much for granted that we sometimes overlook how vital a commodity it is to our existence. Without water there would be no life of any kind on the Earth, and without water readily available in adequate quantity and free of pathogenic organisms human development is tremendously hindered. Sir Harold Hartley recently listed eight 'limiting factors' which might handicap the economic progress of mankind, and at the head of his list he placed shortage of water. From the time when early man first settled by a natural spring or permanent stream, down to the modern atomic power station consuming some 3,600,000 tons of coolant a day, water has been vital.

One urgent world-wide problem which faces mankind to-day is the organization of pure water for small communities in rural areas, backward countries and under-developed localities. Although no precise figures are available, it is quite certain that millions of man-days of labour are lost annually and much distress is caused because of illness and death from water-borne diseases. This tremendous problem can only be met by the organization of pure water supplies in adequate quantity and by proper sanitary measures.

It is the aim of this forty-second monograph of the World Health Organization to provide the basic information for government officials and health administrators who face this challenge. The monograph is essentially a practical handbook for civil and sanitary engineers, medical officers of health and public health administrators, and it describes in a clear and concise manner the ways and means of organizing rural water-supply in order to satisfy basic personal hygiene. Methods of installing various types of water-supply systems from both underground and surface water sources are detailed, together with a consideration of treatment under rural conditions and problems of distribution and use. The monograph concludes with a section on the management of water-supply schemes and a lengthy list of appendixes dealing with a wide variety of topics of value to the engineer working in remote areas.

It seems fairly clear from experience already gained that in most small communities in under-developed areas more health benefits can be gained from money spent on a water-supply programme than in any other way. The supply, however, must be adequate in both quantity and quality and not prohibitive in cost if the hygienic standard of the community is to be raised to a new level. There is, in fact, a remarkable degree of correlation in many communities between standards of living and consumption of water *per caput* per day. This new monograph should help materially in raising the water consumption, hygienic conditions and standards of living of many small communities at present held back by poverty-stricken conditions, high incidence of disease and death, and lack of knowledge.

W. G. V. BALCHIN

REACTIVE METALS

Reactive Metals

Edited by W. R. Clough. (Metallurgical Society Conference, Vol. 2.) Pp. xiv+610. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1959.) 113s.

THIS book presents the papers and discussion from the third Reactive Metals Conference of the American Institute of Mechanical Engineers in 1958. We have grown accustomed to the reporting of conferences in the United States, and this one follows standard practice. There is no visible sign of any theme or thread of continuity in the papers, except the commonly accepted classification of reactive metals, which here includes the transition metals of Groups IV, V and VI A of the Periodic System, together with uranium. The papers are grouped under properties and applications, titanium alloys; nuclear, consolidation, powder techniques, melting and refining; physical metallurgy, temperature effects, phase relationships, interstitial effects; metal processing and fabrication. As a summary of recent American work in very specific fields, such a collection may be of interest to large research and development organizations, but is more likely to be a reference book for the library than resident on the shelves of an individual.

A light-hearted discourse characterizes some of the papers, and, as so frequently happens, the bibliography does not include appropriate European work. The odd references to British papers are

occasionally obscure ones (for example, U.K. Atomic Energy Authority Technical Notes) considering that the same work has often been published in the journal of a learned society. Two contributions on vanadium alloys, by Karl F. Smith and R. J. Van Thynne, discuss the requirements of fuel cladding materials in fast fission reactors. The argument follows very closely that published in Britain some three years ago, and seems to contradict the previous American point of view expressed at the Geneva conference later in 1958.

The most interesting work described is that on titanium alloys and the physical metallurgy of molybdenum, vanadium and niobium. It is a great pity that the Americans still persist in referring to 'columbium' in spite of international agreement to the contrary. There is also a strange reference on p. 7, in the keynote address by D. J. McPherson, to the use of 'columbium' in one U.S. reactor and its planned use in one British reactor. So far as I am aware the use of niobium in the Dounreay fast reactor was first suggested in 1963 and was fixed by early 1956, some years before the Conference to which this book relates.

C. R. TOTTLE

PLUTONIUM AND ITS ALLOYS

Extractive and Physical Metallurgy of Plutonium and Its Alloys

Edited by W. D. Wilkinson. (Based on a Symposium held in San Francisco, California, February 16-17, 1959.) Pp. x+314. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 79s.

ANY information on plutonium is welcome, and the freedom of discussion noticeable since the first Geneva Conference on the Peaceful Uses of Atomic Energy has led to many more symposia of the type presented in this book.

The contents are classified as the title suggests; but an introductory first chapter summarizes, very neatly, the properties of the six allotropic forms, the necessary safety precautions in handling, and discusses the solid state of the plutonium atom.

Six papers on extraction metallurgy cover a wide field, from conversion of salts to metal to removal of fission products by liquation. One American paper reports work between 1943 and 1946, and, in contrast, a French contribution refers to 1956. Detailed results are quoted for extraction coefficients in the distribution of plutonium and impurity elements between nitrate solutions and tri-butyl phosphate. This section on extraction processes will be of value to the chemical engineer working in this field, although one imagines that perhaps some of the information is already well known to those receiving security guarded reports.

The physical metallurgy papers are extremely interesting for metallurgists. A general treatment of the alloying potential of the metal is followed by articles on plutonium alloys containing cerium and zinc. The metallographic techniques required and the transformation characteristics are also referred to with respect to the metal and its alloys. References are given at the end of each paper, and an annotated bibliography and subject-index at the end of the book.

Illustrations and diagrams are well presented, and in spite of the comparatively high price, the nature of the subject matter will ensure a demand for it. Anyone concerned with nuclear energy topics should find this a valuable source of information, additional to, and in a more manageable size, than the proceedings of the Geneva conferences. C. R. TOTTLE

INSTRUMENTATION, DATA PROCESSING AND AUTOMATIC CONTROL

Progress in Automation

Vol. 1. Edited by Dr. Andrew D. Booth. Pp. viii + 231. (London: Butterworths Scientific Publications, 1960.) 42s.

THE editor of this volume defines automation as that field of endeavour which "seeks to duplicate the activities of living creatures, including humans, by non-living but energy consuming means". He goes on to give an excellent historical survey, beginning with the water clock of Vitruvius in 245 B.C. and including many examples of early applications of automatic control. This broad definition is inevitably followed by a wide selection of topics, and the title of the volume is singularly uninformative about their content. In fact, the ten contributors to the volume cover some aspects of British progress in instrumentation, data processing and automatic control.

Articles on instrumentation are contributed by T. B. Rowley and A. E. M. Hodgson. Both are devoted to nucleonic measurement techniques using radioactive isotopes. The first deals with thickness and level measurements and the second with fluid-density measurements, and the combination gives a clear account of these important methods.

Data reduction gives rise to the need for converters to transform the varying analogue quantities in the plant or process into digital form for use by the logger or computer. An excellent contribution by G. J. Herring reviews current practice in analogue to digital conversion and considers in detail a converter designed for use in high-speed data reduction.

The contribution on steel strip mills by G. Syke is a general review of the problems of instrumentation and control in the production of continuous strip. For the chemical industry, J. M. Keating discusses the automatic control of chemical plants and indicates the necessary properties for a digital computer used as a master controller for such a plant. The problems of data processing in an oil refinery are also considered and future developments indicated.

Automatic inspection techniques are discussed by J. A. Sargrove, who considers the possibility of performing statistical analysis on the samples tested and automatically feeding back information to the production line to correct unwanted trends and faults.

There are four articles on machine tool control which form a useful record and are in many ways complementary. K. J. Coppin describes a simple method of machine tool control designed for existing machines. The desired work dimensions are set in by an operator at the start of each traverse and positional measurement is from potentiometers geared to the lead screw.

Two fully automatic numerical control systems are described in articles by D. T. N. Williamson, of Ferranti, Ltd., and F. W. Hartley, of E.M.I., Ltd. The Ferranti system uses optical diffraction gratings with moiré fringe counting to achieve positional measurement and is non-interpolating. The E.M.I. system, on the other hand, uses a continuous analogue measure of tool position and interpolates parabolically between points in the stored programme of successive tool positions. Hartley's paper also contains a comparison of several British and American systems and discusses the economics of numerical machine tool control.

H. J. Finden considers in his paper a numerical control system for a machine tool in which a linear inductosyn gives a precise analogue position measurement independent of the lead screw.

The articles are well written and authoritative, and the choice of topics gives a fair cross-section of British efforts in this vast field.

The volume fills a gap in existing literature between the specialist papers in professional journals and the more popular articles on automation. In this respect it will be of value to many engineers, research workers and administrators who require a sound account of progress in a given topic without searching the literature. It is very well produced, but further volumes may be better matched to their purpose as progress reviews if made in a less costly form.

P. H. HAMMOND

SIGNALS AND STATISTICS

Statistical Theory of Signal Detection

By Dr. Carl W. Helstrom. (International Series of Monographs on Electronics and Instrumentation, Vol. 9.) Pp. viii + 364. (London and New York: Pergamon Press, 1960.) 63s. net.

DR. HELSTROM is primarily interested in the reception of radar signals. He formulates his problems explicitly as problems in statistical inference: to detect a signal in the presence of noise (that is, to decide whether a signal of known form, or perhaps only of known statistical properties, is present or not), to estimate parameters of the signal, such as arrival time and carrier frequency, and to resolve signals, that is, to decide which of a number of known signals are present simultaneously.

After some general material on signals, filters and noise, the author gives a clear description of the Bayes, minimax and Neyman-Pearson decision criteria. Later in the book he describes the use of ratios of maximized likelihoods, and some of the properties of Bayes and maximum likelihood estimates.

The rest of the work consists largely of a detailed application of these methods to the decision problems mentioned above, for situations of varying degrees of complexity: for example, detection when one has nuisance parameters such as signal amplitude, phase and arrival time, or when repeated observations are made on the signal. An aspect of the problem novel to many statisticians is that observations are taken in continuous time, so that the idea of 'sample size' is to some extent replaced by that of 'signal to noise ratio', and the data must be transformed canonically if one is to have an enumerable set of variates.

The solutions to many of the problems are formal, in the sense that they are given in terms of the solution or the eigen values of an untreated integral equation. The author certainly gives a more explicit treatment for several specific cases, and often provides a qualitative appreciation of the results, but it is plain that there is work to be done here. The 'mechanization' of the recommended decision and estimation procedures is touched on only lightly, although, on the other hand, the author claims no more than that he is calculating a "standard of performance against which present systems can be measured", and regarding the optimum systems as guides to design.

The literature references are, perhaps understandably, not always those that a statistician would make. In common with most communications engineers, Dr. Helstrom attributes Cramér's result concerning the spectral representation of a stationary process to Rice, while the Cramér-Rao inequality is credited to Fisher.

These are matters of detail, however, well outweighed by the book's merits, of which the main ones are its clarity, thoroughness and consistent appeal to first principles.

P. WHITTLE

PHOTOGRAMMETRY

Photogrammetry

Basic Principles and General Survey. By Prof. Bertil Hallert. (McGraw-Hill Civil Engineering Series.) Pp. ix+340. (New York: McGraw-Hill Book Company, Inc.; London: McGraw-Hill Publishing Co., Ltd., 1960.) 85s. 6d.

THERE are very few text-books on photogrammetry in English which are sufficiently modern, or which attain a sufficiently high standard of presentation to help the student bridge the very wide mathematical and technical gap between the long-established fundamental principles and modern developments of the subject. The present book goes a long way to remedy this deficiency, and it must rank as an extremely important contribution to the teaching of photogrammetry. There is much new and thought-provoking material, especially in the appendices (which comprise nearly one-third of the book) and in Prof. Hallert's choice and treatment of worked examples.

Earlier text-books pay some sort of lip-service to the idea of statistical treatment of photogrammetric measurements, but none has examined the theory of errors with special reference to the nature of these measurements and the most convenient methods of adjusting them. The contributions of Prof. Hallert in this field are well known, and it is not therefore surprising that one of the most important innovations of this text is a lucid "Introduction of Photogrammetric Theory of Errors" and frequent use of statistical checks in the worked examples.

The most important criticism which must be made is that there is no proper treatment of analytical aerial triangulation. Five years ago this might have been dismissed as a peculiarly British practice, developed by the Ordnance Survey for a special task. In recent years, however, the suitability of the method has been recognized in many other countries, not only for topographical mapping but also in the

applications of photogrammetry to ballistic and satellite research. In this book the part devoted to aerial triangulation deals only with methods of radial triangulation and bridging with plotting machines. The reader is left with the impression that the stereo-comparator is only used for terrestrial photogrammetry. The importance of the camera réseau as the only really satisfactory method of correcting film distortion is not described, despite Hallert's condemnation of the use of a register glass in aerial cameras.

Another remarkable omission is the absence of any description of the more refined methods of analogue adjustment to a block of any sort of aerial triangulation. Slotted templates are, of course, described in some detail, but there is no mention of either stereo-templates or the 'ITC-Jerie' analogue computer. The last is surely one of the most important developments in the whole field of photogrammetry during the post-war period.

D. H. MALING

A HOOKE BIBLIOGRAPHY

A Bibliography of Dr. Robert Hooke

By Sir Geoffrey Keynes. Pp. xix+115+12 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1960.) 50s. net.

THE recent tercentenary celebrations of the Royal Society have cast our minds back to the early years when that illustrious fellowship was enriched by the inventive genius of Robert Hooke. As curator of experiments, secretary and editor, Hooke was constantly active on the Society's behalf, and he may well have saved it from early extinction. But his colleagues failed to appreciate his true worth; he was injured by the enmity of the pre-eminent Newton, and his fame suffered a posthumous eclipse which persisted for two centuries. Only in our own day, and largely through the advocacy of Prof. E. N. da C. Andrade, has Hooke received something approaching proper recognition as a pioneer in many branches of science and as Wren's trusted associate in the immense task of rebuilding London after the Great Fire.

Hooke's few published works, now rare, afford but little idea of the immense range and fertility of his inventive capacity as it is revealed in the records of the Royal Society over many years. Much of this recorded material became generally accessible some twenty-five years ago through the publication of R. T. Gunther's volumes on Hooke in his "Early Science in Oxford". Light was cast from another angle on Hooke's enigmatic personality by the editing of his "Diaries". But the archives of the Society and other repositories preserve many still unpublished manuscripts and letters by or relating to Hooke, the location and contents of which are not generally known to students and which should be taken into account in any final assessment of the man and his age.

A concise, serviceable bibliography of all this material has now been compiled by Sir Geoffrey Keynes in fulfilment of a plan conceived many years ago in discussions with the late Prof. John Fulton of Yale. It opens with a prefatory account of Hooke's career and of the problems facing his bibliographer, passing thence to a discussion of the continuation of Bacon's

"New Atlantis", by "R. H. Esquire" and dated 1660. Sir Geoffrey inclines to the belief that this was, in fact, Hooke's first published book. Other sections deal with Hooke's early tract on capillary attraction, his controversy with Auzout, the "Micrographia" and its derivatives, the six Cutlerian Lectures, the "Philosophical Collections" which Hooke edited to fill a gap in the sequence of *Philosophical Transactions* caused by Oldenburg's death, Waller's edition of the "Posthumous Works", Hooke's contributions to the *Transactions* and to contemporary books, and, finally, the "Diaries". Following the bibliography proper are four appendixes: these comprise a summary list of Hooke's papers and letters preserved in manuscript, a list of letters from printed sources, a selection of books and articles bearing upon Hooke, and, lastly, Newton's notes on the "Micrographia" which have not been transcribed before.

The book is excellently produced, and its interest is enhanced by the inclusion of reproductions of the title-pages and of a few historic plates from Hooke's works; there are also drawings of the College of Physicians which he designed. Sir Geoffrey Keynes has fashioned a tool which will prove indispensable to students of the life and times of Newton's greatest rival.

A. ARMITAGE

AN INTERPRETER OF WHITEHEAD

Whitehead's Philosophy of Science

By Dr. Robert M. Palter. Pp. xv + 248. (Chicago: University of Chicago Press; London: Cambridge University Press, 1960.) 60s. net.

THERE are probably several reasons why Whitehead's contributions to philosophy have suffered some neglect, and even a little discredit, with the passage of years. One is the difficulty of his language and symbolism, another his concern with metaphysics. A great mathematician—now no longer living—once told me how shocking it was to write so obscurely as "A. N. W."; yet the same authority declared—just as Whitehead did in so many words—that metaphysics must be firmly based on science for its survival; and furthermore, that it needed to be critical of itself before it applied the lash to others.

Although the present book is not quite the first and only attempt at interpreting Whitehead, it is assuredly the fullest and most understanding yet produced. If, some forty years ago, one could have had Prof. Palter's work at hand when reading "An Enquiry concerning the Principles of Natural Knowledge" and "The Concept of Nature", many hours of frustration might at least have been shortened. In a sense, the later publications were easier to grasp, because their purpose was clearer, and the author's goal more squarely in view.

As things are now, it seems likely that Whitehead's method of extensive abstraction and his philosophy of organism will prove of current interest, and these are well discussed and illustrated in the present volume. Moreover, the latter subject is set fair to offer an epistemological basis for the coming biophysics. In this context, the quotations from Whitehead, copious as they are, fit naturally into the picture, without being tedious or destructive of the author's careful exegesis. An example is the way in which Whitehead is shown to be fully aware that

natural science means the observation of things as they are, and that to rely on formal mathematical concepts alone is to perpetuate the errors of the scholastics. In fact, a few lines before this remark, Whitehead states bluntly that "If there be no stuff to appear, there can be no space" ("The Principle of Relativity", p. 39). All this shows that he was no pedant with regard to natural science.

A footnote to p. 5 rescues, from rather out-of-the-way sources, Whitehead's pregnant hint to the effect that some day aesthetics will become founded on symbolic logic. There are straws in the wind that way already.

Finally comes the concept of 'fields'. At the weakest, this means "any theory involving continuous distribution in space of some physical magnitude . . .", and at the strongest, any expression of fundamental laws as partial differential equations. It could scarcely be better said, and subsumes most of the substance of the great period of æther physics.

However complex, nothing can detract from the peculiar beauty of Whitehead's prose. His preface to "The Principles of Natural Knowledge" is pathetically lovely in its restrained sense of poignant sorrow.

I was with "A. N. W." shortly before his death: the mind was clear and the memory nearly perfect, as he looked into the Great Unknown.

F. I. G. RAWLINS

THE NEW FOREST

The New Forest

By Juanita Berlin, Edwin Cohen, Dr. Gordon J. Copley, H. L. Edlin, Oliver Hook, Juliette de Baitach Levy, F. E. W. Venning, H. Widnell, W. R. Myers, and Sir Berkeley Pigott. Pp. x + 201 + 27 plates. (London: Galley Press, Ltd., 1960.) 30s. net.

IN view of the wealth of material and scholarship that could have been drawn on, as well as the publicity given to this book, one had reason to expect an authoritative work on the New Forest. Instead, we are presented with an odd and unbalanced assortment of topics that fail to fulfil the claims put forward by the chairman of the Forestry Commission in his foreword.

In an opening chapter entitled "The Background", brief references are made to Stone Age, Bronze Age and Iron Age cultures, and to some of the commoner place names, but there is no attempt to recount or explain the fascinating history of the Forest or the communities who came to settle within its precincts. On the other hand, the chapter on "The New Forest Commoners" deals adequately with the remarkable, if complicated, administration that has evolved through the centuries.

The geology is inadequately dismissed in four pages, and as the contributor admits, much of it is "very briefly and crudely summarized". The distribution of the distinctive Forest soil types is omitted altogether. The same chapter contains a much larger section entitled "Botany", but this deals almost exclusively with pure floristics, and misses completely the opportunity to elaborate the general vegetational pattern in relation to geology and topography. Much later in the book, and separated from the general botanical section, is a rather whimsical, but

nevertheless informative and readable chapter on medicinal herbs.

In the chapter on "Mammals" the part that deals with the history, distribution and hunting of deer is adequate and competent. For the remaining mammals, except the squirrels, there is virtually nothing that relates them to the New Forest as distinct from Britain as a whole. The list of mammals is accurate.

The contribution on "Birds" is awkward in style, and there is an attempt to cram too much information into too short a space—especially when four pages of the thirteen are devoted to one species and the remaining nine pages to 150 species.

One begins to appreciate the atmosphere of the Forest in the chapter on "Perambulation Today", and Edlin's contribution on "Silviculture" is clear, authoritative and interesting.

Some of the remaining chapters and appendixes could have been omitted without loss. There is a strange collection of illustrations; a few of them are well chosen, many contribute little to an appreciation of the New Forest, and quite a number are poorly reproduced. There is no index to the book.

L. E. TAVENER

ADVENTURE, BEAUTY AND SCIENCE IN AFRICA

Serengeti Shall Not Die

By Dr. Bernhard and Michael Grzimek. Pp. 344 (67 plates). (London: Hamish Hamilton, Ltd., 1960.) 30s. net.

THIS is the book of the film. Despite the many fine illustrations, the book cannot compete with the film in showing the space of the Serengeti National Park and the beauty of its animals in motion. But the book is complementary to the film in revealing the careful preparation, the hard work and the risks of the task undertaken by Dr. Grzimek and his son, and it gives a moving insight of their relationship.

It is a true adventure story. After the success of their first film "No Room for Wild Animals", the Grziméks offered part of its revenues for purchase of land to increase the Serengeti National Park, but were persuaded instead to study the animal populations there; that study entailed learning to fly, and that entailed getting permission from their wives.

When these difficulties had been overcome, they made the trip to Tanganyika in their small slow aeroplane, contending with weather and officialdom, gaining sidelights on the countries through which they passed; readers who knew the Sudan before independence will find the account of the Christmas party at Juba very probable and very funny.

The book digresses from the Serengeti and contains much interesting material on the history of East Africa, and of Tanganyika in particular. Some of the opinions about Africa in general may not be shared by those who have worked there; for example, a man who lives in an isolated thatched hut may take a lively interest in world affairs; when visiting a small island on Lake Victoria in 1941, I was asked, "What will happen to France after the war?" Some

may doubt the claim of a chapter heading "Knowledge of Men Lessens Philanthropic Feelings, Understanding Animals Heightens Love". Does it always?

There is a sense of urgency about the book, of the futility of proclaiming Nature reserves without the staff to look after them. But there is no occasion for the fatalistic attitude "Africa is dying and will continue to die". The wild and domestic animals and the people recovered quickly from the awful suffering and death when rinderpest swept through Africa in the last century; that was one of a sequence of major catastrophes revealed by the layers of hard and soft soil in some steep river banks, evidence of alternating erosion and recovery.

Erosion in the Serengeti is not due only to the Masai cattle. In tropical countries, wherever continued trampling forms hard tracks, as on the migration routes of the wild animals, there is some erosion, though not so intense as that caused by large herds of cattle. It is stated, "A National Park must remain a piece of primordial wilderness to be effective. No men, not even native ones, should live inside the borders". But later, "During our flights Michael and I also noted the *bomas* of the Masai and counted their herds. We found only a fraction of the number usually given. Unless their numbers rise and their cattle multiply because of modern protective injections, the Masai might not make such bad neighbours of the Park after all".

That opinion is reassuring. The Grziméks not only carefully counted the wild animals of the Serengeti and found that they amounted to less than 400,000 instead of the supposed million, they also traced their migrations; the animals which graze near Lake Victoria, both inside and outside the National Park, from July until November, are living in the Conservation Area, where the Masai have grazing rights during January–May.

The Grziméks also studied the plants and found that much of the pasture most palatable to wild animals was growing where the Masai kept their stock. Samples of soil were taken for analysis to discover if its composition could be correlated with the distribution of the better grasses; and that also may be correlated with the intensity of grazing, for climax grasses are too tall to suit small antelopes. But just as it was necessary to make many flights to count the animals on parallel strips, so also the vegetation of the Serengeti could be accurately described only by recording the plants on a series of parallel transects across the National Park.

Such plant recording is one of the many urgent lines of research which might be done from the Michael Grzimek Memorial Laboratory at Seronera, the Park headquarters; for Michael Grzimek, twenty-four years old, was killed when a griffon vulture collided with his aeroplane. His tombstone on the edge of the Ngorogoro crater states "He gave all he possessed for the wild animals of Africa, including his life".

"Serengeti Shall Not Die" is an account of scientific work. Some of it is controversial; none of it is dull; it is enlivened by many beautiful plates in colour and in black and white. It should be widely read, and it is to be hoped that many of the readers will show their appreciation in a practical way, by sending to the Director, Tanganyika National Parks, Arusha, a contribution to the Memorial Laboratory and thus help preservation and improvement of the Serengeti National Park.

A. S. THOMAS

SHORT REVIEWS

Foods and Feeding Habits of the Pedi

With Special Reference to Identification, Classification, Preparation and Nutritive Value of the Respective Foods. By Dr. P. J. Quin. Pp. xvii+278+134 plates. (Johannesburg: Witwatersrand University Press, 1959.) 70s.

DR. QUIN provides in this monograph an excellent summary of his work on Bantu nutrition in the Union of South Africa. Although he confines it to the Pedi tribe, most of the data are equally relevant for other Southern Bantu tribes, and social anthropologists, economists, and nutrition experts as well as agriculturists, botanists and entomologists from all parts of Africa will find it a mine of concise and accurate information on the food and feeding habits of the Southern Bantu. The early chapters deal with the plants, animals, reptiles and insects both domestic and wild which enter into Pedi diets. The reader is given not only their local Pedi, English and Afrikaans names but also their scientific names, and in many cases their nutritional composition. Where they happen to form a significant element of Pedi diet this is given in considerable detail; for example, one species of flying ant which the Pedi call *dintlwa* and the entomologists *Carebara vidua* contain, when in the flying stage, 25.2 per cent crude protein in the case of the male and 7.4 per cent in the case of the female. These chapters are followed by an examination and analysis of particular Pedi dishes and the work ends with a discussion of the Pedi dietary pattern, of modern tendencies in Southern Bantu dietary habits and of Pedi health. The supporting tables, plates and drawings are first class and there is a useful bibliography.

G. I. JONES

Religion in Plato and Cicero

By John E. Rexine. Pp. vii+72. (New York: Philosophical Library, 1959.) 2.75 dollars.

THIS interesting little book bears what amounts to the *imprimatur* of Prof. A. D. Nock, from whom the author has absorbed—and made his own—much of the recent classical tradition of Harvard University. It is an excellent record. These two law-givers, Plato the philosopher and Cicero the orator, have seldom been studied synoptically, and their aims compared. Plato is metaphysical, and important for us to-day is his attempt to set up the first system of natural theology. Cicero insists on the usefulness of the gods to the State, if they are properly handled. In any such plan, sanctions are always at hand to deal with offenders, whether poets or otherwise.

Historically, the significance for scientific thought is the clear indication that the Deity can be known from the study of natural phenomena. Later centuries were to bring mankind experience of a less optimistic kind, leading to a severe limitation of Platonic religion. In a word, Plato's conception is a preview of the *deus philosophorum* with whom the Christian God cannot be inconsistent, but who is transcendent, and to some extent 'wholly other'. With this in mind, the author's thesis is most illumin-

ating at the present stage of epistemological development in both theology and natural science.

For such a slender volume, there is a generous bibliography, well calculated to help further reading.

The Structure of Scientific Thought

An Introduction to Philosophy of Science. By Dr. Edward H. Madden. Pp. ix+381. (London: Routledge and Kegan Paul, Ltd., 1960.) 35s. net.

THIS volume is curiously constructed; it is an anthology the members of which are knit together by a series of introductions to each section. Thus, the value of the whole assemblage depends as much on the quality of these prefatory remarks as it does on the choice of the contributions themselves. The author's aim is to help students to understand the way in which scientific thought has been built up, taking examples from physics, probability, biology, psychology, axiology and so on, and presenting them in their original form. There are full references and an adequate bibliography.

Maybe this method will succeed in the United States: one cannot imagine it doing so in general, if only because the selection is so arbitrary, and somewhat weighted in favour of American sources. This is not necessarily a defect, but it tends to limit the book's appeal. The style of the several introductions is rather tiresome; there is much too much "you", as if the reader needed constant prodding. But the writer's heart is in the right place, he upholds science as a truly humanistic discipline, supreme in its own domain, and never self-conscious about being merely useful or fashionable.

The format of the collection is very attractive, though the large page size, carrying double columns, seems quite needless for a work of this character, and makes it difficult to house in an ordinary bookshelf.

F. I. G. RAWLINS

No Stone Unturned

An Almanac of North American Prehistory. By Louis A. Brennan. Pp. xii+370+8 plates. (London: Victor Gollancz, Ltd., 1960.) 25s. net.

THIS is a book written to propagate the idea that man first reached America more than 30,000 years ago, and that his development thereafter was completely independent and owed nothing to contacts with Asia. Only with the coming of the higher civilizations of Mexico and Peru does the author allow that something "cryptically oriental" began to "hover" over them, though he will not have anything so simple as long sea-voyages to account for it, but rather a chain of vanished islands which filtered the oriental influences into an attenuated form.

Mr. Brennan is a journalist by profession and his speech agrees thereto, but he is also a keen amateur archaeologist and knows the literature. He argues his case with great ingenuity, but not always with judgment. One of the weakest features of the whole thesis

is the doubtful character of the evidence for man in America at dates of the order claimed; the instances cited are well known—Santa Rosa Island, Tule Springs and Lewisville—but Mr. Brennan does not make it clear that they are very far from commanding wide acceptance as evidence of the presence of man. As to subsequent contacts, opinions differ a good deal about their extent, but he is a bold man who will have no contact at all by way of the north Pacific, either in the last stages of the Wisconsin glaciation when the Bering Straits were dry or later in boats. To deny such contacts on negative evidence in a very imperfectly explored area, when one is prepared, as the author is, to entertain the idea of a land bridge to bring the makers of Clovis points across the Atlantic to become the Solutreans, is to show a ridiculous lack of balance.

This is not an archaeological text-book. Readers who have knowledge of American archaeology may find parts of it stimulating and a good deal exasperating. Those who do not should take it with a large grain of salt.

G. H. S. BUSHNELL

The Searching Mind in Medicine

By William A. R. Thomson. Pp. 187+25 plates. (London: Museum Press, Ltd., 1960.) 21s. net.

A SERIES of talks, by leading authorities, on the External Series of the British Broadcasting Corporation has been converted into an attractive book by William A. R. Thomson, the editor of *The Practitioner*. Because of the pace with which changes are taking place in modern medicine, however, little remains of the original articles, although Thomson acknowledges the inspiration of the broadcasters and continued help to ensure that his material is accurate and up to date.

The articles are varied and, besides the not unexpected topics of antibiotics, viruses and the effects of radiation on man, the author deals openly and factually with the biochemistry and chemotherapy of cancer. Perhaps too much is made of existing knowledge to show causal relationship between behaviour and physique, but the chapters on memory and learning, the problem of ageing, life at low temperatures and climate and working efficiency will be of interest not only to non-medical readers but also to general practitioners whose reading may have been somewhat circumscribed. The text is concise and carries an air of authority of one who has dug deep for his facts. It is perhaps a little unfortunate, therefore, that Thomson sometimes fails to apply a searching mind to his own beliefs and gets hoist with his own petard. His statement, for example, that "the exceptional handler of men—whether doctor, army officer or teacher—has a shrewd idea of what manner of man an individual is by looking at him" would be accepted by all except those who had subjected their 'shrewd ideas' to the process of statistical investigation.

KATHLEEN M. HAWKINS

Understanding Weather

By Sir Graham Sutton. (Pelican Book, No. A469.) Pp. 215+4 plates. (Harmondsworth, Middx.: Penguin Books, Ltd., 1960.) 3s. 6d.

IN this welcome book the Director-General of the Meteorological Office makes no claim to have written a comprehensive account of the science of

meteorology, and indeed certain aspects of the subject—like air masses and fronts, basic elements of our everyday weather experience—are rather scantily treated. He is not much concerned either with geographical influences, such as the distribution of land and sea and the great mountain ranges, on the global circulation. Also while there is an excellent chapter on micrometeorology (as might be expected), local weather is strangely neglected (although plate 3b refers to a "sea-breeze front" which is nowhere mentioned in the text).

These omissions accepted, here nevertheless is an authoritative and up-to-date guide to a great deal of current thinking in meteorological science. Almost half the book is devoted to an account of modern methods of forecasting. This begins with the conventional techniques of synoptic analysis and forecasting, and goes on to Sutchiff's development theories and Rossby's long waves (for which the way has been well prepared in earlier pages); the author then proceeds to numerical forecasting, from Richardson to the electronic computer (only here does an occasional mathematical equation intrude into an otherwise descriptive treatment), and finally offers a sober assessment of the possibilities of long-range forecasting. As an exposition on a popular level of the professional meteorologist's approach to his subject, this little book is excellent value.

M. PARRY

Comparative Anatomy

By Prof. William Montagna. Pp. x+397. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1959.) 48s. net.

THIS is a well-planned book which introduces the student to the important principles of comparative anatomy, organogenesis and embryology. The author first deals with the characteristic features of vertebrates and the development of the body plan and body tissues. Then follows a short chapter on the Chordata, including useful tables. The skin is next considered, then the endoskeleton, the muscular system, the digestive system, the circulatory system, the respiratory system, the excretory system, the reproductive system, the sense organs and the nervous system. Finally, there is a short chapter on the endocrine glands.

In most of the chapters there is a general introduction, then the development of the system is described and thereafter the comparative anatomy in amphioxus, cyclostomes, fishes, amphibians, reptiles, birds and mammals. At the end of each chapter there is a helpful summary and a short bibliography. The author has rightly emphasized embryology more than is the usual practice in a book of this kind, since developmental events give a better understanding of anatomical detail. There is also a useful glossary at the end of the book.

The book is written well, the descriptions are simple and easily understood, and there are numerous well-labelled illustrations and photomicrographs. It is indeed more difficult to write a simple account of important principles than a detailed text-book and in this the author has truly succeeded. He is to be congratulated on producing a useful, easily read, short account of comparative anatomy which should be of great value to the student. The publishers, too, are to be congratulated on their excellent production of this volume.

T. NIOOL

An Introduction to Embryology

By Prof. B. I. Balinsky. Pp. xiv+562. (Philadelphia and London: W. B. Saunders Company, 1960.) 54s.

DR. BALINSKY has produced a most valuable text-book, in which he has, in his own words, "endeavoured to present embryology as a single science, in which the descriptive morphological approach and the experimental physiological approach are integrated. . . . The subject . . . includes such topics as post-embryonic development, regeneration, metamorphosis and asexual reproduction. Lastly, I believe that embryology cannot be presented adequately without establishing some connection with genetics".

In the past few years, two or three similar attempts have been made; for example, the outstanding "Entwicklungsphysiologie" of Alfred Kuhn in 1956, and the collective work "Analysis of Development" edited by Willier, Weiss and Hamburger in the same year. Balinsky's work is, in the choice of subjects, illustrative material and interpretation, much more similar to the only other one-man English book of this kind, Waddington's "Principles of Embryology" of 1956. It is somewhat surprising to find that this work, unlike the other two, is not mentioned in the text or bibliography.

In spite of its very wide field, Balinsky's book gives a quite thorough treatment of the topics selected for discussion. The material is very up-to-date, and plentiful references are given to recent contributions. The book is also well illustrated, with figures and diagrams chosen more for their relevance to recent physiological interests than to serve as mere morphological descriptions in the manner usual in the older embryological texts. The index is unfortunately rather inadequate. This is, however, a minor fault in a work which will be very useful as the most up-to-date general treatment of embryology as a unified science.

Faune de France No. 63

Coléoptères Scarabéides. Par Renaud Paulian. Deuxième édition, revue et augmentée. Pp. ii+298. (Paris: Editions Paul Lechevalier, 1959.) 5,500 francs.

THIS second edition of the "Faune de France" volume on scarabaeoid beetles has been increased in size by some 60 pages. Changes in comparison with the first edition, which was published in 1944, are almost entirely additions. These provide more detailed information on life-histories, variation, distribution and keys for the identification of larvæ, in so far as the larvæ are known. Eight new species and two new subspecies of scarabaeoid beetles have been added to the list of French species since 1944, making a total of 261 species. This gives an indication of the wealth of the French fauna, for the corresponding number for the British Isles is 68.

The work contains keys which permit complete identification down to species and varieties, and each species is described in detail with a summary of its biology and distribution so far as these are known. Experience with the first edition has shown that the keys work easily and that the figures are adequate. The indexes to predators and parasites and to host plants are a useful addition.

The author has made an attempt to use the infra-specific categories in a consistent and logical manner and to this end defines species, subspecies, race, form and aberration in the preface. The use of the term 'race' is confusing and as defined here is the equivalent of ecophenotype. Aberrations are defined as accidental variations, often unique. This being so, there seems little value in giving keys to enable them to be identified. These are, however, minor defects in a work which has proved its worth.

E. B. BRITTON

Wild Animals of the British Isles

A Guide to the Mammals, Reptiles and Batrachians of Wayside and Woodland. By Dr. Maurice Burton. (The Wayside and Woodland Series.) Pp. ix+180+111 plates. (London and New York: Frederick Warne and Co., Ltd., 1960.) 17s. 6d. net.

THIS is another beautifully bound book in the "Wayside and Woodland" Series, containing 48 excellent colour plates from photographs and 63 interesting black and white illustrations. It is the usual compact size, so would be suitable for carrying in the pocket on a ramble. In all, 58 species of amphibians, reptiles and mammals (excluding marine mammals) are included, whether as rare as the red deer, as localized as the wild cat, or as common as the house-mouse. Each is dealt with simply and in a straightforward manner, some at greater length than others. The various animals are described, each under its own name, in the following sections: insect-eaters, flying mammals, gnawing animals, flesh-eaters, hoofed animals, lizards, snakes and amphibians. These sections are preceded by a helpful introduction, and there is an index at the end of the book.

This would be a most useful addition to a school library. It would be invaluable to the young naturalist as the accounts are both clear and accurate, and would greatly assist identification. Many adults would also find this a pleasing book.

B. J. G. MITTLAND

Dangerous Marine Animals

By Bruce W. Halstead. Pp. x+146. (Cambridge, Maryland: Cornell University Press; London: Putnam and Co., Ltd., 1959.) 4 dollars; 30s.

IN this semi-popular, well-illustrated handbook, Dr. Halstead gives an account of marine animals that bite, sting or are poisonous to eat. He states that "it is not the purpose of this manual to throw needless scares into the skin-diving populace, but rather to point out some known facts regarding dangerous marine organisms, and to show what to do about the situation, if worse comes to worse".

He describes and illustrates each organism (and where appropriate, the venomous apparatus), including also the latest information on medical aspects, treatment and prevention. He has cast his net wide, from coelenterates to marine reptiles and seals, and his handbook will be particularly useful to the aqualung diver, the biologist and the medical practitioner as the first compact guide to the subject.

Dr. Halstead appears to have listed all the important vertebrates, but among the invertebrates many dangerous creatures remain to be generally recognized. In the coelenterates, for example, the author identifies a total of eleven species (out of a total of 25 stingers

listed by me after considerable searching of the literature). His list ranges from such mildly irritating shore anemones as *Actinia equina* and *Anemonia sulcata* to the deadly sea wasp (*Chiropsalmus*) that can kill in 3-8 min. Moderately severe stingers, like the coral reef hydroid *Lytocarpus*, the medusae *Chrysaora*, *Pelagia*, *Lobonema* and the *Stephanoscyphus* stage of *Nausithoe* are not mentioned.

Likewise, we lack precise information for many other invertebrate groups on how many species are potentially dangerous. This is mentioned here, not in criticism of Dr. Halstead's most useful and up-to-date synopsis, but to indicate that our knowledge in this field is far from complete. W. J. REES

Insects and their World

By Harold Oldroyd. Pp. viii+139 (60 plates). (London: British Museum (Natural History), 1960.) 7s. 6d. net.

SO MUCH is known about the teeming millions of insects that to write about them both accurately and simply is by no means easy. Mr. Oldroyd is therefore to be congratulated on providing for the general public and for elementary students of insects a very useful introductory text. He touches lightly on their classification, structure, physiology, behaviour, adaptations and their importance to man. The style is always lucid, avoids technical jargon and is pleasantly illuminated by shafts of wit.

The only disappointment was to find in so lavishly illustrated a book that the plates had so little relation to the interesting stories told in the text. Scarcely any of the drawings or photographs show living insects in their natural environment, or attempt to illustrate points in the life-history. Many of the photographs show pinned insects, or dead ones awkwardly posed on rather unsuitable backgrounds. May we hope that in future editions some of the less-suitable photographs will be replaced by appropriate drawings? The drawings already used are good, but rather formal, however; that by Terzi of the blue-bottle makes the photograph facing it appear very crude. The figures and plates should also be numbered in a single series.

The book is well printed on glossy paper and is free from typographical errors. The very few minor errors of fact or interpretation will doubtless be corrected in the future editions which the book deserves. G. C. VARLEY

Advances in Pest Control Research

Vol. 3. Edited by R. L. Metcalf. Pp. vii+448. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1960.) 109s.

THIS, the third volume in the series "Advances in Pest Control", consists of nine articles by different authors who each examine a limited aspect of pest control research. There is a surprisingly extensive inter-relationship between individual essays which enhances their value by providing a wider view of the subject. The volume should prove to be a useful one.

Three essays written around groups of chemicals (organic halide nematocides by W. Moje, dithiocarbamate fungicides by R. A. Ludwig and G. D. Thorn, triazine herbicides by H. Gysin and E. Knipli) differ in emphasis according to the characteristics of the chemicals, pests and crops involved and the reactions between them. The essay on translocation

by J. W. Mitchell, B. C. Smale and R. L. Metcalf clearly shows the wider knowledge of plant structure and function than of the properties which determine the penetration and movement of chemicals in plants. The empirical nature of the use of mixtures of biologically active materials is illuminated by P. S. Hewlett, who discusses the varied investigations on the joint action of insecticides with balanced emphasis. The general lack of understanding of the complexities of the interaction between chemicals and organisms can again be seen in the essay on DDT-dehydrochlorinase by H. Lipke and C. W. Kearns, who barely hint at other possibilities of biological detoxication of DDT. F. P. W. Winteringham describes the labelled pool-technique as a way of searching for the effects of an interaction between chemicals and living organisms together with techniques which make the approach possible. The search for chemicals attractive to insects is reviewed by N. Green, M. Beroza and S. A. Hall, who classify attractants according to the type of response elicited (sex, food) and discuss their possibilities for controlling, or obtaining information about, insect pests. Knowledge and imagination are the bases of the procedure, described by R. C. Bushland, of controlling insects by male sterilization.

K. A. LORD

Blakeslee

The Genus *Datura*. By Aamos G. Avery, Sophie Satina and Jacob Rietsema. Pp. xli+289. (New York: The Ronald Press Company, 1959.) 8.75 dollars.

AN unfortunate title, for this is not, as one might imagine, a revision or monograph of the genus *Datura*, but rather a special kind of *Festschrift* compiled in honour of the late Dr. Albert F. Blakeslee, dealing with various aspects of the biology of a number of *Datura* species. Dr. Blakeslee devoted almost forty years to the study of the 'Jimson weed' (*Datura stramonium*) and its near allies, and this book shows just what can be accomplished by such intensive cultivation of a limited field. The results are certainly impressive, at least so far as genetical and cytological researches are concerned, and, for the taxonomist, it is especially interesting to have minute details of the mechanisms of variation explained on the whole lucidly and with some degree of consideration for those who are not professional geneticists. In this connexion the chapters on polyploidy, extra chromosomal types and gene mutations are particularly enlightening: it is surely by such studies of mechanisms rather than by controversy and hypothesis that the secrets of evolution and phylogeny will be revealed. Readers more concerned with practical problems of plant breeding will find much to interest them in the succeeding chapters on seed development, growth, processes in the embryo and seed, and barriers to crossability. The discourses on chimeras and radiation experiments should appeal equally to the theorist and practitioner. It is perhaps the taxonomist who fares worst in this symposium, for, making all due allowances, it cannot be pretended that the chapters on taxonomy and nomenclature are more than cursory. The section *Brugmansia* is almost wholly neglected, and we are not given any clear guidance as to the status of this group in relation to other species of *Datura*. The phytogeographers are not much better served; the geographical distribution of *Datura* species raises all

sorts of intriguing but unanswered queries. Are there any grounds, for example, for supposing that *D. stramonium* is indigenous in Europe, Asia or Africa? Is *D. leichardtii*, which is seemingly so nearly related to the Mexican *D. pruinosa*, really a native of Australia? Had a qualified taxonomist been privileged to work with Dr. Blakeslee's team, one feels that these questions and many others might have been answered. Deficiencies are almost certain to be found in such 'occasional' literature; but at least it can be said that "The Genus *Datura*" will be a most valuable help in the preparation of future monographs of this very interesting genus.

R. D. MEikle

A Book of Ferns

By Greta Stevenson. Second edition, revised and enlarged. Pp. iv+168. (Hamilton, New Zealand: Paul's Book Arcade, 1959.) 13s. 6d.

GRETA STEVENSON'S "A Book of Ferns", a revised edition of an earlier work, deals exclusively with the ferns of New Zealand. Although not so comprehensive as Crooke's edition of Dobbie's classic, it is, nevertheless, a well-prepared little guide and it is well illustrated with simple line drawings. Primarily intended for the novice, two-thirds of the recorded species are described. The nomenclature throughout is good, if conservative, although authorities for names are unfortunately omitted. Keys based on position of sorus and on habit of growth should enable the reader to determine his plant with comparative ease. One may question the statement that the "best size for a herbarium sheet is 17 in. by 11 in." since the Kew-size sheet, adopted in many herbaria, is 16½ in. by 10½ in. The use of naphthalene, recommended as an insect deterrent, has lost favour these days, being largely superseded by the more effective *paradiichlorbenzene*. Nevertheless, Greta Stevenson's book can be thoroughly recommended as a competent introduction to New Zealand ferns. A good glossary, a list of Maori vernacular names and notes on cultivation complete a work which admirably fulfils its purpose.

F. BALLARD

Trees and Bushes in Wood and Hedgerow

By Helge Vedel and Johan Lange. Translated by C. H. R. Hillman. Adapted by H. L. Edlin. Pp. 224. (London: Methuen and Co., Ltd., 1960.) 16s. net.

THE similarity between the flora of the two countries has made it possible to adapt this book, compiled by a team of Danish foresters and artists, to suit British forest flora. Its aim is to provide a practical reference book to the character and appearance of all trees and shrubs to be found in the open countryside. Specimens grown only in botanical collections have not been included. Each species has a reference number, which simplifies the linking of the various sections.

The book begins with an introduction to five keys. These keys are for the identification of branches with: (1) needle-like or scale-like leaves; (2) opposite compound leaves; (3) opposite simple leaves; (4) alternate compound leaves; and (5) alternate simple leaves.

Next there is a section of excellent coloured plates of 120 different trees and shrubs, with many subsidiary sketches to assist identification. Then follows the section describing each of the 127 species, with small diagrams to explain botanical

details and places of origin. Each is very clearly written.

There are four interesting short sections, namely: "The Tree's Wood"; "The Development of British Forests"; "Forest Tree Breeding"; and "Great Trees".

There are a Latin-English glossary, followed by a glossary of botanical terms and, lastly, an index.

B. J. G. MITTLELAND

Taxonomy of Flowering Plants

By C. L. Porter. (Series of Biology Texts.) Pp. xii+452 (600 illustrations). (San Francisco and London: W. H. Freeman and Company, 1959.) 44s.

THIS is an excellently produced and efficiently written handbook of the taxonomy of flowering plants for North American students. It is not easy to explain in a clear and interesting way the complex matters involved in the principles of taxonomy and nomenclature, but this book comes close to doing so. Within its limitations—it does not pretend to be an advanced text-book, and the plants mentioned as examples or figured are mostly North American—it is hard to find any important fault. The numbers of species assigned to various families and genera seem not infrequently to be on the low side—there are surely more than 5,000 species of Gramineae, but otherwise the text seems excellent. The text-figures and photographs, 600 in all, are unusually numerous and clear and do much in helping to give this book the attractive appearance it has.

J. P. M. BRENNAN

Die Cactaceae

Handbuch der Kakteenkunde. Von Curt Backeberg. Band 4: Cereoideae (Boreocereae). Pp. xxxi-xxxviii+1927-2630. (Jena: Gustav Fischer Verlag, 1960.) 91 D.M.

HERR BACKEBERG'S fourth volume is devoted to the sub-tribe Boreocereinae of the semi-tribe Boreocereae of the tribe Cereae of the sub-family Cereoideae. It thus includes the treatments of such larger genera as *Echinocereus* (73 species), *Pilosocereus* (60), *Cereus* (36) and *Melocactus* (36). Many of the numerous smaller genera have been proposed by the author himself, who defends the recognition of small genera in his foreword. The high standard of the numerous illustrations is maintained. Philatelists will notice (Fig. 2450) the portrayal of *Melocactus communis* on the farthing postage stamp of the Turks and Caicos Islands.

Plant Pathology

An Advanced Treatise. Edited by J. G. Horsfall and A. E. Dimond. Vol. 2: The Pathogen. Pp. xiv+715. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1960.) 22 dollars.

THIS is the second of three volumes intended to provide an advanced treatise on plant pathology. The first dealt with the diseased plant, and this one is concerned with what causes disease. In their prologue the editors indulge in words and definitions, and distinguish between three kinds of pathogen—animate, inanimate and viruses. They are in no doubt that insects are animate pathogens and are under the mistaken impression that insects are

'generally included in plant pathology in Europe', but, nevertheless, they wisely decide in the end to leave them with the entomologist. The opening chapter is a review of the nature, origin, and evolution of parasitism towards commensalism by specialization. Then follow two chapters on the reproduction of viruses, bacteria and fungi. The next six chapters are concerned with the nature of pathogenicity and cover the ability of the pathogen to breach the host by mechanical and chemical means, the importance of toxins, variability in the pathogen, and the inheritance of pathogenicity. There are also important contributions on spore germination and on soil pathogens in relation to the rhizosphere, but these are rather out of place and tend to break the continuity of the central theme.

About three-quarters of the text was prepared in more or less equal proportions by American and English authors. The other four contributions originated in Canada, India and New Zealand. There are comprehensive author and subject indexes and more than seventeen hundred literature references. It can be said now, without waiting for the third volume, that the editors and their advisory board have certainly achieved the task they set themselves in providing research workers and advanced students of applied biology with an exposition on plant pathology which is, in fact, unequalled in the English language.
